Abstract

This work contributes to an understanding of substrate recognition and translocation performed by ABC-transporters. ABC-transporter form one of the largest protein-family of membrane proteins. Classically, they consist of two nucleotide binding (NBDs) and two transmembrane domains (TMDs). This architecture facilitates transport of a large variety of substrates using ATP as energy source in all three kingdoms of life. Among these import and export systems are differentiated. Import systems are so far only found in prokaryotes and archaea and require an additional substrate binding protein (SBP), which binds the substrate in the periplasm or extracellular space and delivers it to the transporter. SBPs of ABC-transporter show all a common architecture: They consist of two domains different in size, in between a deep cleft where the substrate binding-site is located. Crystal structures of various SBPs have shown mainly two conformations: one without substrate (open) and one with substrate bound (close) where the substrate is located in the cleft and the two domains have rotated towards each other. Through structural analysis of SBPs substrate specificity, mechanism of substrate binding and release could be illustrated via the example of the ABC-transporter OpuB from *Bacillus subtilis* and ProU from thermophilic *Archaeoglobus fulgidus*. The contribution to substrate binding of single amino acids in the binding pocket could be resolved both qualitatively and quantitatively for both proteins. For ProX the SBP of ProU molecular dynamics simulation as well as structural analysis revealed a single amino acid that is responsible for switching the affinity of the binding pocket from a rather low affinity state to a high affinity binding site.

Biophysical investigation of full length ABC-transporter requires application of detergents to keep the membrane protein in solution. Establishment of a method for determination of critical micelle concentration (CMC) and aggregation numbers of diverse detergents in various buffer solutions was also one part of this work. Both parameters depend on pH, salt concentration, temperature and polymer concentration in the solution. Thus a reliable and fast analysis of these characteristics is an important advantage prior to start biophysical and structural analysis on membrane proteins.

With such a "toolbox" in hand establishing purification and functional analysis of single components of Type I secretion system of *Escherichia coli* were the next steps. This system, which translocates its substrate Haemolysin A in a single step across two membranes, is composed of three proteins: The ABC-transporter Haemolysin B (HlyB), a so called membrane fusion protein Haemolysin D (HlyD) and the outer membrane protein TolC. The ABC-transporter has a special feature: an additional domain at its N-terminus, which belongs to the family of C39 peptidase domains. However, in HlyB the catalytic relevant residues are mutated and therefore this C39 domain is no longer able to cleave. Homologous

overexpression and purification of the ABC-transporter HlyB and subsequent functional assays showed that ATP hydrolysis of NBDs can be stimulated by the addition of substrate (HlyA). This increase ATPase activity does not occur due to binding of HlyA to C39 domain but binding of the secretion signal of HlyA to the NBDs of HlyB. To further investigate the role of C39 domain in the transport cycle, the protein was overexpressed separately, purified and for structural analysis successfully crystallized.

Zusammenfassung

Die hier vorliegende Arbeit leistet einen Beitrag zum Verständnis der Substraterkennung und Translokation bei ABC-Transportern. ABC-Transporter verkörpern eine der größten Klassen von Membranproteinen. Ihr klassischer Aufbau aus zwei Nukleotidbindenden (NBD)- und zwei Transmembrandomänen (TMDs) ermöglicht den Transport unterschiedlichster Substrate unter ATP-Verbrauch in allen Reichen des Lebens. Dabei werden Import und Exportsysteme unterschieden. Importsysteme sind bisher ausschließlich in Prokaryoten und Archaeen gefunden worden und benötigen zusätzlich noch ein Substratbindeprotein (SBP), welches das Substrat aus dem Periplasma oder dem extracellulären Raum zum Transporter delegiert. Durch Analyse struktureller Daten dieser Substratbindeproteine wird die Substratspezifität, sowie der Mechanismus der Substratbindung und auch des Entlassens des Substrates in die Translokationspore des Transporters an den Beispielen des ABC-Transporters OpuB aus *Bacillus subtilis* und ProU aus dem thermophilen Archaeon *Archaeoglobus fulgidus* erklärt werden. SBPs von ABC-Transportern zeigen alle einen ähnlichen Aufbau: Sie bestehen aus zwei unterschiedlich großen Domänen, in deren Mitte sich die Substratbindestelle befindet. Kristallstrukturen von verschiedenen SBPs haben gezeigt, dass diese eine offene Konformation ohne Substrat und eine geschlossene Konformation, bei der Substrat in der Mitte gebunden ist und die beiden Domänen zueinander rotiert sind, einnehmen können.

Welche einzelnen Aminosäuren die Substratspezifität der Bindungstasche ausmachen, konnte mittels Analyse der Kristallstrukturen des SBPs OpuBC, das ausschließlich Cholin bindet, und einem Vergleich mit homologen SBPs mit verändertem Substratspektrum gezeigt werden. Für das ProX Protein, das SBP des ABC-Transporters ProU, konnte ein detaillierter Ablauf der Substraterkennung, Bindung und der Entlassung des Substrats in die Translokationspore des Transporters bestimmt werden.

Die biophysikalische Untersuchung gesamter ABC-Transporter erfordert die Anwendung von Detergenzien um diese Membranproteine in wässrigen Lösungen zu stabilisieren. Die Etablierung einer Methode zur Bestimmung der kritischen Mizellen Konzentration sowie der Aggregationszahl unterschiedlicher Detergenzien in verschiedensten Pufferlösungen ist ein weiterer Aspekt dieser Arbeit. Beide Parameter sind stark von pH-Wert, Salzkonzentration, Temperatur und Polymeren in der Lösung abhängig. Daher ist eine zuverlässige und schnelle Analyse dieser Parameter ein entscheidender Vorteil, bevor biophysikalische oder strukturelle Analysen an Membranproteinen durchgeführt werden.

Mit diesem „Werkzeugkoffer“ konnte die Reinigung und funktionelle Analyse der einzelnen Komponenten des Typ I Sekretionssystems aus *Escherichia coli* etabliert werden. Dieses System, das das Substrat Hämolyisin A in einem Schritt über zwei Membranen transportiert,

besteht aus drei Komponenten: Dem ABC-Transporter Hämolysin B (HlyB), dem Membranfusionsprotein Hämolysin D (HlyD) und dem Außenmembranprotein TolC. Dabei besitzt der ABC-Transporter noch eine zusätzliche N-terminale Domäne, die in Sequenzvergleichen sich als C39 Peptidasedomäne herausstellte. Allerdings sind die katalytisch relevanten Aminosäuren mutiert, so dass sie nicht mehr in der Lage ist ihr Substrat zu spalten. Die homologe Expression und Aufreinigung des ABC-Transporters HlyB, sowie die anschließende funktionale Analyse haben gezeigt, dass die Hydrolyseaktivität der NBDs vom Substrat HlyA stimuliert werden kann. Dabei konnte nachgewiesen werden, dass diese Stimulation nicht auf eine Bindung an die C39 Domäne hervorgerufen wird, sondern es sich um eine Interaktion des Sekretionssignal mit den NBDs handeln muss. Um die Rolle der C39-Domäne zu verstehen, wurde diese separat exprimiert und aufgereinigt und für strukturelle Analysen erfolgreich kristallisiert.

1. Introduction

Cellular membranes are composed of a lipid bilayer with a hydrophobic core of about 40Å and are therefore impermeable for ions and only partially permeable for hydrophilic substances (1). This cell membrane is essential for bacteria, eukaryotes and archaea since it separates the intracellular space from extracellular environment or in case of eukaryotes for maintaining intra-cellular compartments. It is impossible for amino acids, nutrients, ions and other small compounds to diffuse freely across these membranes. To overcome this barrier prokaryotes, eukaryotes as well as archaea developed distinct transport systems. Referring to the source of energy used one can distinguish channels (2), primary and secondary transporters (3). Secondary active transporters couple translocation of substrate to electrochemical gradients across the membrane, preferably via a proton or sodium potential. Primary transporters such as the proton pumping ATPases or ATP-binding cassette (ABC)-transporters deploy the free energy released upon ATP hydrolysis (4).

1.1 ABC-Transporter

ABC-transporter are found in all three kingdoms of life and form one of the largest membrane protein superfamilies (5-7). ABC-transporter share a common structural organization comprising two transmembrane domains (TMDs) that form the translocation pore and two nucleotide binding domains (NBDs) that bind and hydrolyze ATP (8). These domains can be arranged as a single fused polypeptide chain, as half-size transporters (one TMD and one NBD fused on a single gene) or as four separately encoded proteins (although this is found solely in prokaryotic ABC importers). Import proteins require an additional component, the substrate binding protein (SBP) (7).

Substrates transported by ABC transporters are diverse in nature and size, like for example sugars, amino acids, peptides, vitamins, ions, xenobiotics and even polypeptides, linking these ABC-transporters to various cellular functions that range from energy supply to osmoregulation, detoxification and virulence (9-12). The largest substrate identified until today is a 900 kDa Protein which is secreted by *Pseudomonas fluorescens* WCS365 (13). This remarkable substrate diversity of ABC-transporters is reflected in sequence variance in the TMD domains, whereas NBDs share rather high sequence homology (see below).

To date, there are a small number of crystal structures of full-length ABC-transporters available (Figure 1). However only for a few of the structural characterized proteins additional biochemical information is available. For most of them even the substrates are unknown. On a structural based view, ABC-transporters can be grouped into 3 classes (14). Class I and II

contains ABC-importers, which are distinguished by their arrangement of transmembrane domains and the fact that type I importers contain a substrate binding site in the TMD while type II do not. Type I importer's membrane section is composed of a core of 2 x 5 transmembrane helices (Figure 1), in case of maltose permease one subunit possesses one extra helix while the other has actually two additional helices. Type II ABC-transporters exhibit around 2 x 10 core transmembrane helices and helices from each subunit form distinct and separate domains.

Figure 1: Crystal structures of ABC-transporters. First row: Type I ABC-Importers: ABC-transporter ModBC in complex with its SBP ModA (pdb: 2ONK), putative methionine transporting MetNi (pdb: 3DHW), maltose transporter MalFGK₂ in complex with its SBP MalE (pdb: 2R6G); second row: Type II ABC-transporter: BtuCD with BtuF bound (pdb: 2Q19) and HI1470 (pdb: 2NQ2); third row: Type III Exporters: P-glycoprotein from mouse (pdb: 3G60), Sav18660 (pdb: 2ONJ) and *E. coli* MsbA (pdb: 3B5W).

Figure 1 shows crystal structures of full length ABC-transporters known to date. Twining of the TMDs around a hypothetical axis perpendicular to the membrane forms the translocation pathway across the membrane. The NBDs face towards each other thereby the conserved sequence motifs (see below) are positioned at the dimer interface. The similarities in structure support a common mechanism of nucleotide and substrate dependent conformational changes that result in translocation of the substrate across the membrane. The “alternating access” model for transport suggests the presence of a substrate binding site that can alternatively access either the extracellular side or the intracellular side of the membrane, corresponding to the “outward” and “inward” facing conformation of a transporter (15).

The best-characterized system is the *E. coli* maltose transporter MalFGK₂. For more than 30 years it has been studied in different laboratories. This wealth of knowledge accumulated by genetic, molecular genetic and biochemical means was complemented by crystal structures of the isolated MalK dimer (NBDs) in four conformations as well as two conformational states of the full-length transporter more recently (Figure 2) (16-18).

Figure 2: Crystal structures of MalFGK₂ in an intermediate state (pdb: 3R6G)(A) and in the apo-state (pdb: 3FH6)(B). Color code is the following: Maltose binding protein (MalE), blue; MalG, light grey; MalF, dark grey; MalK, orange and yellow. In the periplasm maltose is bound and delivered to the transporter by MalE. There it induces a conformational change towards a closed conformation by interacting with the periplasmic loop of MalF (A). This change is communicated to the NBDs and induces ATP-hydrolysis. When ADP is present in the binding pockets of the MalK dimer it opens and forces also the TMDs to change to the cytoplasmic open state (B).

Figure 2 represents two snapshots of the transport cycle. Figure 2A shows the full ABC-transporter including its substrate binding protein in an ATP-bound state. Liganded MalE (SBP) initiates the transport cycle by binding to MalFGK₂. It communicates the presence of a substrate to the large periplasmic loop of MalF (Figure 2A). Thereby ATP hydrolysis is initialized by MalK and the formed ADP forces the NBD-dimer to open. This conformational change forces the TMD to change to inward facing conformation (Figure 2B) and substrate can be released into the cytoplasm. Not only crystal structures led to the understanding of this particular transport mechanism also biochemical data on single domains, as well as parts and the full-length transporter supply the required information to interpret these structures (19-22).

To analyze the role of the individual domains that comprises an ABC-transporter, I established purification protocols and biophysical analysis tools to get further insights in regulation of transport, requirements for functionality and structural information.

1.1.1 Nucleotide binding domains

The NBDs of ABC-transporters are also called "motor domains" as they fuel the translocation process. NBDs share a conserved architecture among all ABC-transporters, importers as well as exporters. They consist of a RecA-like and an α -helical subunit (23, 24), connected by two flexible loop regions, one of which contains a conserved glutamine residue (Q-loop). The RecA-like domain harvests the Walker A and B motifs, indicative of the presence of a nucleotide binding site (Walker A: G-X-X-G-X-G-K-S/T, Walker B: ϕ - ϕ - ϕ - ϕ -D, where ϕ is a hydrophobic residue)(25, 26). Walker A motif is responsible for binding of the β - and γ -phosphate groups of ADP or ATP, while Walker B motif is arranged as a β -strand, whose terminal aspartate coordinates a Mg²⁺ ion through water needed for ATP hydrolysis (27). Moreover, NBDs contain an H-loop with a conserved histidine residue that contacts the γ -phosphate of ATP and is required for hydrolysis (28), and finally the famous "signature" motif, the C-loop (L-S-G-G-Q) (29), which identifies a amino acid sequence as an ABC-transporter.

NBDs function as dimers in the assembled transport protein, with the nucleotide binding sites of each monomer facing towards the other (head-to-tail arrangement). In this conformation ATP is mainly bound via residues of the Walker A motif of one monomer and the C-loop of the other monomer. One model based on experiments on MalK suggests that upon binding of ATP, the NBD dimer closes in a 'tweezer-like'-fashion (16). Hydrolysis of ATP occurs in the tightly dimerized state, which then reopens to release phosphate. The ADP-bound conformer of the NBD dimer resides in an intermediary, semi-open state, which presumably returns to the open apo-state after the dissociation of ADP (17). The observed positive cooperativity of ATP-hydrolysis (28) makes it highly likely that two molecules of ATP are needed for NBD dimer closure (7, 16).

In Chapter I the assayed NBD of the ABC-transporter OpuA from *Bacillus subtilis* differs from most other NBDs but similar to MalK in that it possesses an additional C-terminal domain of approx. 150 amino acids. In the 'tweezer-like'-motion a dimer of these accessory domains act as the bottom of the tweezer and keeps the two monomers together during the catalytic cycle. Sequence alignments have shown that the accessory domains of OpuAA from *B. subtilis* as well as its homologue OpuAA from *Lactococcus lactis* contain two cystathione β -synthetase domains (CBS)(30). For OpuAA from *L. lactis* it was observed that these CBS domains are involved in sensing osmotic stress and activate the transport function of OpuA (31).

Förster resonance energy transfer was used to analyze the conformational changes taking place during and after ATP-hydrolysis. As a model system the above-mentioned OpuA NBD from *B. subtilis* was chosen. Former publications have shown that it has dynamic monomer-dimer equilibrium, hydrolyses ATP *in vitro* and dissociates in the ADP-bound state (32). For fluorescence experiments single labeled OpuAA is required. As OpuAA itself has no cysteine, single mutants were introduced for labeling. Purification and characterization of several mutants resulted in two accessible labeling positions. Both mutants of OpuAA (S45C, G161C) were stable enough to work with and had remaining ATPase activity.

Förster resonance energy transfer is based on overlapping fluorescence and absorption spectra of donor and acceptor fluorophores (Figure 3A). Measuring acceptor fluorescence intensity of different mutants of OpuAA results in distance information between the labeled amino acids (Figure 3B).

Figure 3: A: Spectral overlap of OregonGreen fluorescence and TexasRed absorption. These are the two fluorophores used in the study presented in Chapter I B: Homology model of OpuAA based on crystal structure of MalK (pdb: 1Q1E). Depicted is the putative ATP-bound dimeric state. Conserved motifs are highlighted and color-coded as follows: Walker A (blue), ABC-signature motif (purple), Walker B (yellow). Cysteine mutations at position S45 and G161 are accentuated in red and green, respectively. Red and green lines indicate the distances between these two residues.

As NBDs of ABC-transporters share rather high homology it was possible to build a homology model based on *E. coli* MalK and to refine it due to the distant restraints obtained with this fluorescence study.

1.1.2 Substrate binding proteins

In prokaryotes, ABC transporter are involved in the uptake of a large variety of substances, including nutrients, osmoprotectants and signal molecules. All ABC import systems require an additional component, a substrate specific receptor or binding protein for function (SBP). These substrate binding-proteins bind their ligands with high affinity either in the periplasm of Gram-negative bacteria, where they can diffuse freely between the inner and outer membrane or linked to the cell surface with a N-terminal lipid moiety in archaea and Gram-positive bacteria (33). For some archaea it is also observed that they are inserted in the membrane via a N-terminal hydrophobic helix and even in some bacteria SBPs are directly linked to the TMDs resulting in two or even four substrate binding sites (34)(Figure 4).

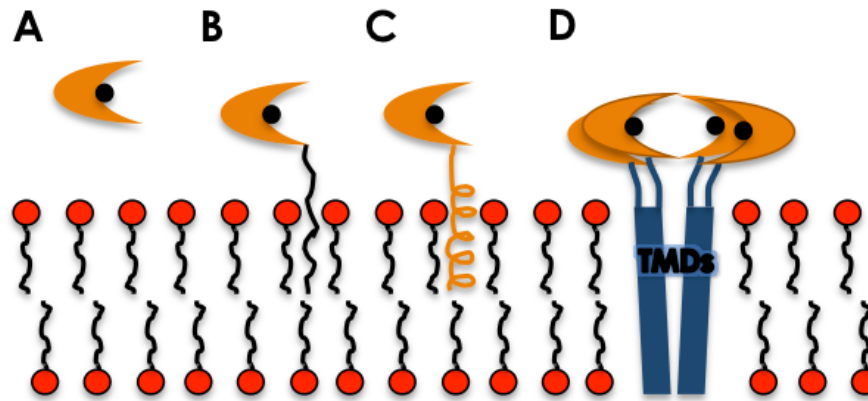

Figure 4: Structural organization of substrate binding proteins in different organisms. A: In Gram-negative bacteria SBP can diffuse freely in the periplasm. **B:** in Gram-positive bacteria and archaea that have no outer membrane SBPs are fused to the membrane via an N-terminal lipid modification. **C:** In some archaea SBPs are linked to the membrane via an N-terminal hydrophobic helix. **D:** In some bacteria and archaea transporters with two or four SBPs directly linked to the TMDs are found.

Despite the absence of significant sequence similarity across SBPs and the diversity of ligands bound, all of the SBPs have a common overall organization. This comprises two globular domains of similar topology, each of which contains a central β -pleated sheet flanked by sets of α -helices (Figure 5)(35-38). Shown in Figure 5 is the structure of glycine betaine/proline betaine binding protein ProX from *Archaeoglobus fulgidus*. It illustrates the two-lobe architecture of SBPs. The connection of the two domains is one of the differentiating factors among SBPs and is highlighted in orange.

Figure 5: Overall fold of substrate binding proteins. Presented is the structure of ProX from *Archeoglobus fulgidus* in the glycine betaine bound state (A) (pdb: 1SW2) and ligand-free (B) (pdb: 1SW5) (39). The ligand is shown as stick representation. Highlighted in orange are the two loops connecting both domains.

Upon substrate binding, the two lobes twist and close, thereby entrapping the ligand, therefore the ligand binding mechanism is called Venus flytrap (40)(Figure 5). For one of the most analyzed SBPs the maltose binding protein (MBP) from *E. coli* it has been shown in NMR studies, that the two domains of MBP are dynamic and fluctuate around an average orientation that is only slightly more closed than this observed in the open conformation found in the crystal structure. This means that the binding of the ligand forces the two domains to close. But how this can be established on a molecular level is still unclear.

In Chapter II crystallization and subsequent structure determination of ProX Y111A from *A. fulgidus* at 2.0 Å resolution is highlighted. Surprisingly the protein adopts a rather open conformation although the substrate (glycine betaine) is bound in the binding pocket. Further analysis of the structure and molecular dynamics simulation enabled us to identify a crucial residue that is involved in triggering domain closure and also communicating with the transmembrane section for release of the substrate. When a ligand enters the binding site a network of amino acid side chains communicates the presence of it towards Arg149, which increases ligand affinity and induces domain closure. These results are corroborated by

molecular dynamics studies and support the view that a single amino acid acts as a switch to induce the high affinity state of the SBP

The observation of highly homologous SBPs with different substrate specificity lead to the question what are the molecular determinants for specificity as well as affinity of SBPs. Therefore crystal structures of OpuBC from *B. subtilis*, which is highly specific for choline betaine (CB), ProX from *A. fulgidus*, that only binds glycine and proline betaine (PB, GB) and structure of OpuCC from *Straphylococcus aureus*, which is rather unspecific and virtually binds all osmolytes, are compared in Chapter III.

1.2 Obstacles to overcome: studying ABC-transporters *in vitro*

It is challenging to analyze these membrane transporters *in vitro*. This is reflected in the rather low number of structures available until today (one archaeal, six bacterial and one eukaryotic ABC-transporters (Figure 1)). For biophysical and structural analysis one has to extract the protein from its natural environment (the lipid bilayer) and keep it “happy” in an artificial solution. Although there are several experimental opportunities to do so, it requires lots of work.

The most commonly employed method to study membrane proteins in aqueous solution is micelle-forming detergents. Detergents are amphiphilic molecules consisting of a hydrophobic and a hydrophilic portion. At concentrations below their specific critical micellar concentration (CMC), detergent molecules exist as monomers in aqueous solution. Above the CMC, multimeric detergent micelles assemble that are in a highly dynamic equilibrium with detergent monomers. A large number of detergents with a wide range of chemico-physical properties are available (for an overview see www.affymetrix.com, www.emdbioscience.com/calbiochem, www.sigmadrich.com). However detergents are often not optimal for the activity and stability of a membrane protein (41). Micelles are highly dynamic assemblies and their intrinsic instability can result in protein unfolding and aggregation. Additionally, the lateral forces acting on a membrane protein in the roughly spherical detergent micelle are significantly different from those in a native planar membrane (42). Summarizing all these aspects leads to the conclusion that a detergent micelle only poorly mimics the architecture and physical properties of a cellular membrane.

In many cases, the presence of detergent molecules interferes with the experimental conditions required for monitoring protein activity by enzymatic, ligand binding or spectroscopic assays. Furthermore, the particular chemico-physical requirements of a given membrane protein are usually only met by a few, if any, out of the bewildering selection of detergents available today. There is no method that could predict a compatible detergent for a given membrane protein a priori. Therefore the search for a suitable detergent that

stabilizes a functional state of the membrane protein is highly empirical as well as time-consuming.

Figure 6: Schematic representation of detergent solubilized (A) and in nanodisc reconstituted membrane protein (B). The membrane protein is shown in black, detergents are colored in pink and lipids in green. Picture is taken from Raschle et al. (43).

For this reason alternative solubilisation techniques are highly desirable and are more and more in use these days. Alternatives that mimic the native lipid bilayer are liposomes and so called nanodiscs. In the case of liposomes, limited solubility, the formation of multilamellar vesicles and the inaccessibility of the vesicle interior may, however, interfere with functional investigations. Recently the self-assembly of a lipid bilayer nanodevice named nanodiscs has been established (44, 45). Nanodiscs consist of an assembly of phospholipids arranged as a discoidal bilayer, surrounded by amphipathic apolipoproteins (Figure 6)(43). In their native context, apolipoproteins assemble into roughly spherical high density lipoprotein particles, responsible for the reverse transport of cholesterol from the peripheral tissues to the liver (46). The native-like environment provided by the nanodisc is likely to support both protein stability and functionality of an incorporated membrane protein.

1.3 Biophysical Methods: Analyzing Detergents

After analyzing components of ABC transport systems, the next step was to investigate full-length transporters and protein complexes containing an ABC-transporter. Therefore the usage of detergents to keep them soluble in water based buffer systems is required (see section 1.2). The amphiphilic detergents cover hydrophobic patches at the surface of the protein while their hydrophilic head groups point towards the buffer containing outside.

For the analysis of membrane proteins and here especially ABC-transporters one starts with a membrane preparation of your expression host, extract the protein of interest with a high amount of detergent and then follows at least one step of protein purification. Finally pure protein can be analyzed biochemically and structurally. For every step the "right" detergent is required. If micelle size is too small, the protein might aggregate, if one uses too much detergent, detergent micelles containing the protein will accumulate maybe not reversible and thus inhibiting protein function, etc. Thus many different kinds of detergents (ionic, non-

ionic, zwitter-ionic, one alkyl chain, two alkyl chains, etc.) are available until today and still this number is increasing (see Figure 7).

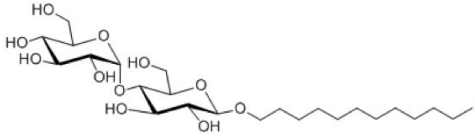

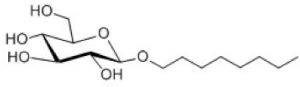

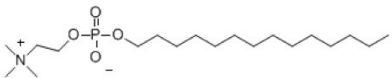

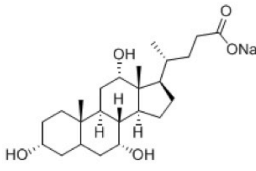

Structure	head group characteristic	Name
	non ionic	N-Dodecyl- β -D-Maltopyranoside (DDM)
	non ionic	N-Octyl- β -D-Glucopyranoside (OG)
	zwitterionic	Fos-Choline 14 (FC-14)
	zwitterionic	n-Dodecyl-N,N-Dimethylamine-N-Oxide (LDAO)
	ionic	Sodium cholate
	ionic	Sodium dodecyl sulfate

Figure 7: A few examples of commonly used detergents (structural representations are taken from www.affymetrix.com).

There are several characteristics of a protein detergent system one must keep in mind during screening for a good alternative for the selected protein. The most famous and important ones are the critical micelle concentration and aggregation number of the detergent.

The CMC is defined as the concentration of a detergent above which micelles are formed spontaneously. The other feature is the number of monomers per micelle, so called aggregation number. In Chapter IV the establishment of a robust and easy to use assay for the determination of both characteristics in a nearly high throughput manner is presented.

1.3.1 CMC determination

As an easy to measure output information the methods described uses the fluorescence of the dye Hoechst 33342, which is applied in biochemical labs for DNA staining *in vitro*. It is cell permeable and emits blue light when it is bound to DNA. For this kind of application these features were used to detect the point when micelles of detergents are formed. Therefore

there is a need for a hydrophobic compound that is soluble in water but partitions greatly and immediately into micelles when they are formed and then it should change some physical properties that can be measured. This is exactly what the fluorescence dye Hoechst 33342 offers: It diffuses greatly into micelles and does almost not emit fluorescence light in hydrophilic media while it emits bright blue light in the micellar phase (Figure 8) (47).

Figure 8: Hoechst Fluorescence in detergent micelles. A: Below the CMC almost no Hoechst 33342 fluorescence is detectable. B: Reaching the CMC detergent micelles form, Hoechst 33342 diffuses into the micelles and due to the hydrophobic environment inside Hoechst emits fluorescent light. C: Increasing detergent amounts lead to formation of more micelles and an increase in fluorescence signal is detectable until all Hoechst is in the micellar phase.

If one measures Hoechst 33342 fluorescence at increasing detergent amounts, one receives a curve like that depicted in Figure 2. There almost no fluorescence of Hoechst is detectable until a concentration of DDM of 0.007 % (w/v) is reached. This inflection point indicates the CMC for this specific detergent.

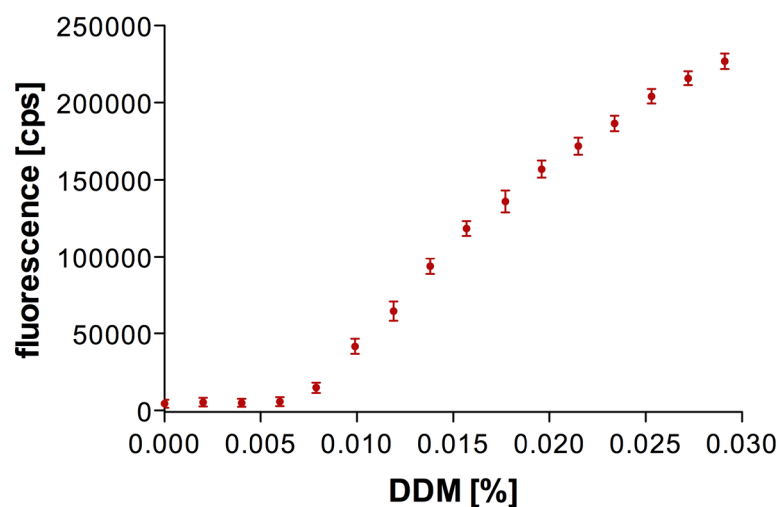

Figure 9: CMC-Determination for DDM. Plotted is the fluorescence signal at 457 nm. Inflection point indicates the formation of micelles (0.007 % DDM).

This kind of measurements can take place in a fluorescence spectrometer but also in a 96well microtiter plate reader that is available in virtually every biochemical lab (see Chapter IV).

1.3.2 Calculating aggregation numbers

The micellar aggregation number (N_{agg}) represents the number of detergent molecules or monomers found in a micelle. Analogous to a molecular weight determination for polymers, the N_{agg} represents an „averaged“ value for a collection of micelles, which individually are dynamic structures capable of exchanging monomers among themselves. Several highly sophisticated methods are available to determine this micellar parameter (ultracentrifugation, EPR, SAXS, SANS, NMR, X-ray, Light scattering, etc.). The most convenient one for biochemists is obviously fluorescence measurements. Most biochemical labs are equipped with fluorescence detection. Currently, both steady-state and time-dependent fluorescence measurements have been applied to the determination of aggregation numbers (48). Steady-state fluorescence is the more common used technique, since it is inexpensive and experimentally simple. They usually rely on the decrease or “quenching” of a fluorescence probe associated with the micelle through the presence of a second species, the “quencher” (Figure 10). How fluorescence quenching varies with increasing quencher concentration is then determined. Several probe-quencher combinations have been investigated (49-51). The system worked depends on the pyrene fluorescence quenched through Hoechst 33342, which is described in more detail in Chapter V.

Figure 10: Pyrene quenching upon addition of Hoechst 33342. A: Pyrene emits fluorescence light as no quencher is present. B: Pyrene fluorescence in micelles that possess pyrene and Hoechst 33342 is quenched.

Given several assumptions about probe-quencher interactions and behavior (both are entirely in the micellar phase, the distributions of the quencher and the probe obey Poisson statistics and the probe only fluorescence in the absence of the quencher (50)), a mathematical expression relating the ratio of fluorescence intensities to the total detergent concentration, free detergent concentration and quencher concentration can be derived. Initially the expression

$$\frac{I}{I_0} = e^{-\frac{[Q]}{[M]}} \quad \text{Equation 1}$$

relates, relating the ratio of fluorescence intensities in the absence (I_0) and presence (I) of quencher to the quencher concentration $[Q]$ and the micelle concentration $[M]$. The micelle concentration is given by

$$[M] = \frac{[Det] - [Det_{free}]}{N_{agg}} \quad \text{Equation 2}$$

There $[Det]$ is the total detergent concentration $[Det_{free}]$ is the concentration of detergent monomers not associated with micelles and N_{agg} the average number of detergent monomers in each micelle. Substitution of equation 2 into equation 1 results in:

$$\ln\left(\frac{I}{I_0}\right) = -\frac{N_{agg}[Q]}{[Det] - [Det_{free}]} \quad \text{Equation 3}$$

Thus the aggregation number can be determined from the slope of a linear fit of $\ln(I/I_0)$ when knowing the detergent concentration in the assay and the CMC.

In Chapter V the practicability of the probe-quencher pair pyrene – Hoechst 33342 is demonstrated and several examples where CMC and aggregation number determination should be considered for biochemical purposes are given. To make it applicable for nearly every biochemical lab we applied our method to 96well plate reader available in virtually every lab.

1.4 Type I secretion in *Escherichia coli*: A multi protein complex including the ABC-transporter HlyB

A Type I secretion machinery in *Escherichia coli* allows the translocation of a 1023 amino acid big protein (Haemolysin A, HlyA) from the cytoplasm to the extracellular medium in a single step, without periplasmic intermediates (52, 53). This machinery consists of three proteins localized in the cell membranes. In the inner membrane there is the ABC-transporter HlyB located, which first recognizes the substrate via its secretion signal and is therefore responsible for the specificity of the secretion process. HlyD, a so-called membrane fusion protein consists of a short cytoplasmic domain at the N-terminus followed by a membrane helix and a large periplasmic domain (54). It is thought that this protein mediates the connection between the outer membrane tunnel TolC and the ABC-transporter HlyB (see Figure 11 for schematic representation).

Figure 11: A: Schematic representation of Type I secretion system of *E. coli*. HlyB (shown is the crystal structure of Sav1866, pdb: 2ONJ) resides in the inner membrane. The additional domain (C39) is indicated as blue circle. HlyD is shown in purple. It interacts with the ABC-transporter and the outer membrane protein TolC in the periplasm (pdb: 1EK9), the cytoplasmatic interaction partner is not known so far. **B:** Schematic drawing of the transported toxin Haemolysin A. Secretion signal of 50-60 amino acids is located at the C-terminus (dark blue). Ca^{2+} -binding motifs are highlighted in green. For its toxicity HlyA requires acylation at two indicated lysine residues. In dark grey a putative hydrophobic membrane insertion domain is shown.

In addition to its two TMDs and NBDs, HlyB has an extra domain at its N-terminus of approximately 150 amino acids. Sequence alignments identified these 150 amino acids as a C39 peptidase domain. This family of peptidases cleaves their substrates after a double

glycine motif (55, 56). However, the C39 domain of HlyB is degenerated and therefore inactive in terms of cleavage. As secretion of the toxin is completely abolished if the C39 domain is deleted the question arises which role does this domain play in substrate recognition and transport.

By separating the C39 domain from the transporter genetically and subsequent overexpression and purification, it was possible to crystallize the oligomeric C39 protein. The crystals diffract X-rays nicely and a X-ray data set up to a resolution of 2.0 Å was collected of the single domain. With these data structure determination should be possible which would provide us with insights into putative interaction sides, oligomeric state of the domain and its function in the transport process (see Chapter VI).

Another approach to get insights on the business of C39 domain are functional studies on the full-length transporter and a truncation mutant lacking this domain (HlyB Δ C39), which is presented in Chapter VII. Therefore I established overexpression and purification of the transporter and performed ATP hydrolysis measurements. Overexpression could be achieved homologously in *E. coli*. As described above detergent screening is a challenging step on the way to pure, stable and active membrane protein preparation. Membrane extraction in the case of HlyB could only be accomplished with the detergent Foscholine-14. However using it on further steps of purification yield in stable but inactive protein. Thus exchange of detergent during affinity chromatography was tried. A screen of several detergents identified C₁₂E₈ (Dodecyl-octaethyleneglycolether) as a suitable detergent to do activity measurements on this protein. ATP concentration dependent analysis did not follow Michaelis-Menten kinetics but fitted very well to a cooperative fit yielding in a Hill coefficient of 2. This is in good agreement with studies on isolated NBDs (57)(Figure 12).

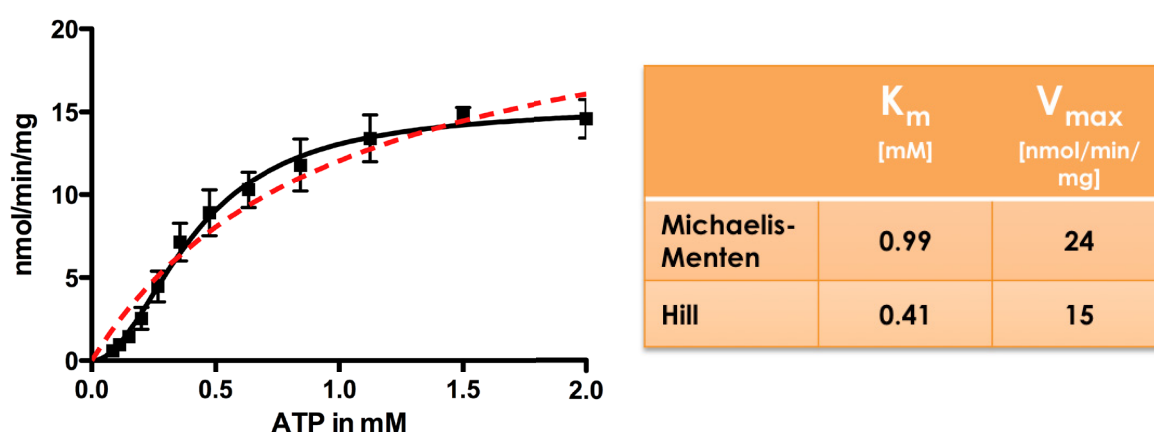

Figure 12: Kinetic data of HlyB wild type. Black straight line belongs to fit function considering cooperativity. Red dashed line shows Michaelis-Menten fit function.

To see whether C39 domain has an influence on ATPase activity we analyzed substrate dependent activity. Thus HlyA was secreted and purified from supernatant. A comparison of wild type and HlyB Δ C39 activity is shown in Figure 13.

Figure 13: HlyA dependent ATPase activity of wild type HlyB (black) and Δ C39 mutant.

HlyA stimulates ATPase activity of both wild type and Δ C39 protein. However effect on the truncated protein is more than six fold higher. Thus the C39 domain has a regulatory influence in the transport process, making sure that ATP is not wasted. These results are in good agreement with reduced growth of cells overexpressing HlyB Δ C39. As no stimulation could be detected for HlyA lacking the C-terminal secretion signal, this part of HlyA must bind to the transporter and induce ATP consumption. In this coherency especially the role of the N-terminal putative cytoplasmic part of HlyD would be interesting to analyze. First experiments provided hints that it interacts with C39 domain. If this domain is lacking ATPase activity is completely abolished after addition of HlyD.

The ABC transporter (ATP-binding-cassette transporter) OpuA is one of five membrane transport systems in *Bacillus subtilis* that mediate osmoprotection by importing compatible solutes. Just like all bacterial and archaeal ABC transporters that catalyse the import of substrates, OpuA (where Opu is osmoprotectant uptake) is composed of an ATPase subunit (OpuAA), a transmembrane subunit (OpuAB) and an extracellular substrate-binding protein (OpuAC). In contrast with many well-known ABC-ATPases, OpuAA is composed not only of a catalytic and a helical domain but also of an accessory domain located at its C-terminus. The paradigm of such an architecture is MalK, the ABC-ATPase of the maltose importer of *Escherichia coli*, for which detailed structural and functional information is available. In the present study, we have applied solution FRET (Förster resonance energy transfer) techniques using two single cysteine mutants to obtain

initial structural information on the architecture of the OpuAA dimer in solution. Analysing our results in detail and comparing them with the existing MalK structures revealed that the catalytic and helical domains adopted an arrangement similar to those of MalK, whereas profound differences in the three-dimensional orientation of the accessory domain, which contains two CBS (cystathionine β -synthetase) domains, were observed. These results shed new light on the role of this accessory domain present in a certain subset of ABC-ATPase in the fine-tuning of three-dimensional structure and biological function.

Key words: ABC (ATP-binding-cassette)-ATPase, conformational changes, dimer, Förster resonance energy transfer (FRET), osmoprotection.

INTRODUCTION

Osmoregulation is of crucial importance for cell viability and survival [1]. *Bacillus subtilis* has to maintain a cell turgor of approx. 20 bar (1 bar = 100 kPa) [2], which is believed to be the driving force of cell expansion. Thus any change in external osmolarity will induce passive influx (hypo-osmotic stress) or efflux (hyperosmotic stress) of water, thereby changing cell turgor [3,4]. Hyperosmotic conditions (an increase in the extracellular osmolarity) result in the uptake of K⁺ ions as a first line of defence to maintain cell turgor in *B. subtilis* [5]. However, the accumulation of a large concentration of a charged ion is detrimental to many cellular functions such as protein function and/or protein–DNA interactions. Thus *B. subtilis* switches to a second line of defence and starts to actively take up or synthesize so-called ‘compatible solutes’ [6]. In the phyla of bacteria, these ‘compatible solutes’ are small molecules such as sugars, polyols, amino acids, quaternary amines, sulfate esters or small peptides [7]. The common denominator of all these compounds is the fact that they are highly soluble and bear no net charge under physiological conditions. As a consequence, compatible solutes counteract the deleterious effect of changes in the extracellular osmolarity by equilibrating concentration gradients across the cellular membrane and maintaining cell turgor [4]. In addition

to their well-studied role in maintaining an appropriate level of cell water and turgor, compatible solutes also act as protein stabilizers both *in vitro* and *in vivo*. Although the molecular action of compatible solutes as a ‘chemical chaperone’ is poorly understood, the common opinion is that these molecules act according to the ‘volume exclusion model’ [8].

Extensive research in the last two decades has identified five transport systems providing osmoprotection in *B. subtilis* through the uptake of compatible solutes [6]. In concert, these five importers allow *B. subtilis* to cope with osmotic stress due to the ability to utilize common compatible solutes such as proline, choline, ectoine, glycine betaine or proline betaine. All of the Opu (osmoprotectant uptake) systems operating in *B. subtilis* belong either to the class of secondary transporters (OpuD and OpuE) or to a subfamily of primary transporters, the ABC (ATP-binding cassette) transporter family (OpuA, OpuB and OpuC; for a recent review see [9]). These membrane transporters ultimately use the energy of ATP for substrate translocation across biological membranes [10]. Although found in all three domains of life and involved in many vital cellular processes, ATP-dependent transporters share a basic blueprint that is composed of four modules: two NBDs (nucleotide-binding domains or subunits) harbouring the ATPase activity and two TMDs (transmembrane domains or subunits) that form the translocation pathway. Next

to the substrate, ABC transporters can be classified by the directionality of transport: import or export. OpuA belongs to the family of ABC importers, since it catalyses the import of glycine betaine and proline betaine from the extracellular medium into the bacterial cytosol. Additionally to the NBD (OpuAA) [11] and the TMD (OpuAB) [9], this family always requires another component for functionality: a so-called SBP (substrate-binding protein; OpuAC in the case of the OpuA transporter [12]). Recent insights into the molecular function of these ABC transporters were provided by X-ray crystallography that determined the high-resolution structures of isolated NBDs (for a recent review see [13]) and intact ABC transporters [14–19]. For example, crystal structures of the NBD of the maltose import system (MalK) in the nucleotide-free, ATP- and ADP-bound states have deciphered many of the molecular principles that govern ATP binding and hydrolysis and have resulted in the proposal of a ‘tweezer-like motion’ that accompanies maltose import [20,21].

OpuAA, the NBD of the OpuA transporter, and MalK, the NBD of the maltose importer, share interesting similarities. Both NBDs not only are composed of a catalytic and a helical domain that harbours all conserved sequence motifs of these ATPases such as the Walker A and B motifs and the hallmark of ABC transporters, the C-loop or ABC-signature motif [10], but also contain an accessory domain, which is composed of approx. 150 amino acids and is located C-terminal to the canonical NBD (catalytic and helical domain). In the case of MalK, this accessory domain interacts with at least two enzymes, MalT [22] and enzyme IIA [23], thereby regulating the expression of the maltose operon. Furthermore, in the ‘tweezer-like motion’ model, the accessory domains act as the bottom of tweezers keeping two NBDs together during a catalytic cycle, whereas the canonical part (the catalytic and helical domains) undergoes ATP-induced dimerization remaining monomeric in the nucleotide-free and ADP-bound states.

Biochemical studies have established that OpuAA undergoes a dynamic monomer–dimer equilibrium and forms dimers in the nucleotide-free and ATP-bound states but, in striking contrast with MalK, becomes monomeric in the ADP-bound state [11]. The closely related OpuA glycine betaine importer in *Lactococcus lactis* has been intensively studied in the past by biochemical approaches [24]. Like OpuAA from *B. subtilis*, the NBD of the *L. lactis* homologue is composed of a canonical part (catalytic and helical domain) and an accessory domain. Most important was the fact that the accessory domain contains the fingerprint of two CBS (cystathionine β -synthetase) domains [25] and is involved in sensing osmotic stress signals that activate the transport function of the *L. lactis* OpuA system [26].

In the present study, we have applied FRET (Förster resonance energy transfer) studies to analyse the structure of OpuAA in solution by monitoring and determining the conformational changes taking place during the catalytic cycle of the ATPase. After generating suitable single cysteine mutants of OpuAA, static and time-resolved FRET measurements provided a set of distance restraints that were employed to model the overall structures of OpuAA in the nucleotide-free, ATP- and ADP-bound states based on the available crystal structures of MalK [20,21]. Surprisingly, the three-dimensional positioning of the accessory domains with respect to the canonical part of the NBD was different, whereas the overall conformational changes during the catalytic cycle were identical with the ones determined previously for other isolated NBDs [20,27–29]. Thus our results provide novel insights into the architecture of OpuAA from *B. subtilis* and suggest that the accessory domains play an important role in the structural and functional regulation of these proteins.

MATERIALS AND METHODS

Cloning, expression and isolation of OpuAA single cysteine mutants and the F19W mutant

To change native amino acids to cysteine, 5′ and 3′ fragments were amplified by PCR using pBAD33/OpuAA as a template and flanking/mutagenic primer pairs as follows: S45C, 5′ CH7/CH29 and 3′ CH8/CH28; G161C, 5′ CH7/CH41 and 3′ CH8/CH40; F19W, CH47/CH48. The primers are CH7, 5′-GGAATTCATATGAGTGTAGATGAGAAACCAATTA-3′; CH8, 5′-ATATA-TAAAGCTTATTAGTGTGGTGTGGTGTGGTGTTCACCTCC-TGTGCAGAAGGATCTTG-3′; CH28, 5′-ATTAACCCCAA-CGGTACATCCGGTTGCTTTCAG-3′; CH29, 5′-CTGAAAGC-AACCGGATGTACCGTTGGGGTTAAT-3′; CH40, 5′-ATATT-GGTGTTCAAAAACATTCCAGTGGGAACGAG-3′; CH41, 5′-CTCGTTGGACTGGAATGTTTGAACACCAATAT-3′; CH47, 5′-ATTCCTTGTGTTTGTTCGCCCAAATCTTAGAGAC-3′; and CH48, 5′-GTCTCTAAGATTTGGGGGAAAACAACAAGA-AG-3′. Secondly, the mutated *opuAA* gene was amplified using both overlapping fragments as a template and the flanking primers CH7 and CH8. The PCR products were digested with NdeI/HindIII (New England Biolabs) and cloned into pBAD33. All gene inserts were sequenced according to the ddNTP method and were free of mutations. Mutant proteins were produced in *Escherichia coli* and purified by IMAC (immobilized metal-ion-affinity chromatography) as described previously [11]. Monomeric OpuAA was isolated by SEC (size-exclusion chromatography) using a Superdex200 HR 26/60 column (GE Healthcare) equilibrated with buffer A [10 mM sodium phosphate and 0.1 mM EDTA (pH 7.5)] supplemented with 1 M NaCl. Protein-containing fractions were pooled and stored at 4°C until further use.

ATPase activity assays

ATPase activity of monomeric OpuAA was analysed by an enzyme-linked assay as described previously [11] in 10 mM sodium phosphate buffer (pH 7.5) and 1 M NaCl. In brief, absorbance at 340 nm was monitored at 1 min time intervals over a period of 15 min at 22 ± 2°C. Data points of the whole measuring period or until all NADH was consumed (over a period of at least 7 min) were used to calculate linear slopes $\Delta A/\Delta t_{\text{OpuAA}}$. To account for autohydrolysis of ATP, similar assays were performed in the absence of OpuAA. After background subtraction ($\Delta A/\Delta t = \Delta A/\Delta t_{\text{OpuAA}} - \Delta A/\Delta t_{\text{buffer}}$) reaction velocities were calculated according to eqn (1):

$$v = \frac{\Delta A}{\Delta t} \cdot \frac{1}{2590 \text{ M}^{-1} \cdot c_0} \quad (1)$$

In this equation, v is the reaction velocity, $\Delta A/\Delta t$ denotes the linear slopes of the time-dependent decay of NADH absorbance at 340 nm of OpuAA samples after background subtraction, and c_0 is the final concentration of OpuAA. Reaction velocities represent the average value of two independent measurements.

Fluorophore labelling of OpuAA mutants

For site-specific labelling of mutant OpuAA with fluorophore dyes, cysteine-specific maleinimide chemistry was used. Typically, OpuAA was passed over a PD-10 column (GE Healthcare) to remove DTT (dithiothreitol) that was added to prevent disulfide bond formation during storage and mixed at a concentration of 10 μM with 25 μM dye [donor dye: OG (Oregon Green® 488 maleinimide; Molecular Probes), 20 mM in dimethylformamide; acceptor dye: TR (Texas Red® C2 maleinimide;

Molecular Probes), 4.1 mM in methanol] and incubated overnight at 4°C. Protein and free dye were separated using a PD-10 column (GE Healthcare) equilibrated with buffer A supplemented with 10 mM NaCl. To isolate the labelled mutants in a quantitative fashion, anion-exchange chromatography was used to separate labelled and non-labelled OpuAA. After sample loading on to a 1 ml Q-Sepharose HiTrap column (GE Healthcare) equilibrated with buffer A supplemented with 10 mM NaCl, a 12 column volume gradient (0.01–2.5 M NaCl in buffer A) was applied. Elution was followed at 216 nm, 491 nm and 592 nm respectively.

Labelling efficiency and protein concentration

Protein concentration was determined using the BCA (bicinchoninic acid) assay following the procedure provided by the manufacturer (Pierce) using BSA as a standard. To determine the efficiency of fluorophore labelling, the molar absorption coefficient of the isolated dyes was used as provided by the manufacturer (Molecular Probes). However, not only incomplete labelling was evident but also a blue shift of the emission maximum as well as changes in the molar absorption coefficient (up to 2-fold; see Supplementary Figure S2 at <http://www.BiochemJ.org/bj/412/bj4120233add.htm>). Thus an additional purification step to quantitatively separate labelled and non-labelled protein was employed (see above) to circumvent these problems and avoid spectroscopic determination of the labelling efficiency.

MS

Samples obtained from anion-exchange chromatography (OpuAA S45C-OG or OpuAA S45C-TR) or purified OpuAA S45C were desalted over a C₁₈ reversed-phase minicolumn (perfect pure C₁₈; Eppendorf) before mass spectrometric analysis. ESI (electrospray ionization)-MS measurements were performed using a ESI-QqTOF instrument (QSTAR XL, Applied Biosystems) equipped with a nanospray ion source. The ESI-MS spectra were reconstructed using the deconvolution algorithm included in the analyst software (Applied Biosystems).

FRET sample preparation

To measure FRET efficiencies within homodimeric OpuAA, all donors had to be paired with acceptors in the assembled dimer. Therefore OpuAA-TR and OpuAA-OG were mixed in a 9:1 molar ratio. In brief, species were mixed at conditions of dynamic monomer/dimer equilibrium (buffer A + 100 mM NaCl) and concentrated to 30 μM to force dimer formation. After incubation overnight at 4°C, samples were applied to a Superdex200 HR 10/30 SEC column (GE Healthcare) previously equilibrated with buffer A supplemented with 1 M NaCl to isolate the dimeric species. The dimer fraction was used for the FRET assay, whereas the monomer fraction was used only for control experiments. For ADP/Mg²⁺-mediated decay the dimer fraction was diluted into buffer A + 100 mM NaCl.

FRET assays

Fluorescence was measured with a Cary-Eclipse spectrometer (Varian) at a λ_{ex} of 492 nm at a temperature (*T*) of 20 ± 1°C and a slit width of 5 nm in 10 mM sodium phosphate (pH 7.5), 0.1 mM EDTA and 1 M NaCl. In static FRET assays, samples were separately analysed with emission recording from 500 to 650 nm and analysed according to eqn (2) [30]:

$$E_T = \frac{R_0^6}{R_0^6 + R^6} \quad (2)$$

In time-resolved FRET assays, the sample was chased with 10 mM ADP or ADP/Mg²⁺ (pH 7.5) at *t* = 0 to allow dimer dissociation. Fluorescence at time *t* (*F_t*) was followed at 519 nm over a period of 3600 s at 5 s intervals and fitted to eqn (3). In this case, fitting parameters were: fluorescence at *t* = 0 (*F_{t=0}*), fluorescence increase at infinite time (ΔF) and half-time (τ).

$$F_t = F_{t=0} + \Delta F \cdot (1 - e^{-t/\tau}) \quad (3)$$

Amplitudes were used to calculate the *E_T*-time-course according to eqn (4). For *t* = 0 the *E_T* value for the original, nucleotide-free state was extrapolated and using the Förster-distance [*R*₀ = 51 Å (1 Å = 0.1 nm) for the OG-TR pair] of this donor/acceptor pair, its distance in this state was calculated.

$$E_T(t) = 1 - \frac{F_t}{F_{t=0} + \Delta F} = 1 - \frac{F_t}{F_{t=\infty}} = \frac{R_0^6}{R_0^6 + R(t)^6} \quad (4)$$

Intrinsic tryptophan fluorescence measurements of the F19W mutant of OpuAA

All measurements were performed at 22 ± 1°C on a Cary-Eclipse spectrophotometer employing a slit width of 5 nm. Wild-type OpuAA does not contain any tryptophan residues. The tryptophan residue engineered at position 19 of OpuAA was excited at 290 nm, and fluorescence was collected at the emission maximum (350 nm) at a protein concentration of 2 μM dimeric OpuAA in 10 mM sodium phosphate (pH 7.5), 1 M NaCl and 0.1 mM EDTA. The chase was started by adding 1 mM ADP and 5 mM Mg²⁺. Data were analysed using a single exponential decay.

Molecular modelling and structural analysis

Molecular modelling was performed with MODELLER 9v1 [31] employing standard settings. As templates, the crystal structures of MalK in the semi-open, nucleotide-free (PDB entry: 1Q1B), the open nucleotide-free (PDB entry: 1Q1E), the ATP- (PDB entry: 1Q12) and ADP-bound (PDB entry: 1AWN) states were used. The quality of the obtained structural models of OpuAA in the corresponding functional states was verified with PROCHECK [32] and compared with the template structure. The initial models were further modified in O after imposing the FRET-derived distance restraints using sgFRET (<http://www.mpibpc.mpg.de/groups/grubmueller/start/software/frets-g-1.0/frets-g.html>). Structural superimpositions were performed using LSQMAN [33] using the indicated motifs as anchor points. The buried surface areas were calculated using areaimol of the CCP4 suite [33a]. All structural figures were prepared using PyMol (<http://www.pymol.org>).

RESULTS

Biochemical studies have demonstrated that OpuAA from *B. subtilis* undergoes a dynamic monomer-dimer equilibrium [11]. Interestingly, this equilibrium depends on the presence or absence of nucleotides. To gain further insights into the underlying conformational changes, we applied FRET techniques of single cysteine mutants of OpuAA in solution. Since the crystal structures of MalK from *E. coli* are available in the nucleotide-free and ATP- and ADP-bound states [20,21], they provide a lead structure (homology of 69%) for OpuAA homology modelling and would open up the possibility to translate the distance restraints derived from FRET measurements into a three-dimensional model of OpuAA. A homology model of OpuAA using the crystal structure of MalK in the nucleotide-free state (PDB entry: 1Q1B)

Figure 1 Homology model of OpuAA

(A) Homology model of the core domain OpuAA in the nucleotide-free state lacking the accessory domain. The model was generated using MODELLER 9v1 [31] as described in the Materials and methods section. The helical domain is shown in light tan and the catalytic domain in yellow. The OpuAA-specific insertion between β -strands 1 and 2 is highlighted in grey. Conserved motifs are colour-coded as follows: Walker A motif (blue), C-loop or ABC-signature motif (red), Walker B motif (magenta), D-loop (black) and H-loop (green). Positions of the single cysteine mutants are highlighted as spheres and labelled. (B) Sequence alignment of the accessory domains of OpuAA from *B. subtilis* (residues 277–418) and *L. lactis* (residues 271–408) containing a tandem CBS domain (residues 283–335 and 342–394 in the case of OpuAA from *B. subtilis*) with selected proteins containing CBS domains, for which a crystal structure is available. The two CBS domains in OpuAA from *B. subtilis* and *L. lactis* and IMPDH [41] are underlined. TM0892, open reading frame 0892 from *Thermotoga maritima* with unknown function (PDB entry: 1VR9); TM0935, open reading frame 0935 from *T. maritima* with unknown function (PDB entry: 1050); TA0289, open reading frame 0289 from *Thermoplasma acidophilum* with unknown function (PDB entry: 1PVM). (C) Homology model of the accessory domain of OpuAA from *B. subtilis*. The tandem CBS domains are coloured cyan (CBS1) and blue (CBS2) respectively. The N- and C-termini, residues 277 and 418 respectively, of OpuAA are indicated. The model was derived from the crystal structure of TA0289 (PDB entry: 1PVM) due to the high sequence identity (25% identity and 51% homology) and obtained as described in the Materials and methods section.

was generated. As shown in Figure 1(A), OpuAA indeed adopts a ‘MalK-like’ structure [20] composed of a helical (coloured tan) and a catalytic (coloured yellow) domain. The catalytic domain of OpuAA contains a 24-amino-acid insertion between β -strands 1 and 2 (highlighted in grey), which is not present in other ABC domains. However, homology modelling of the accessory domain (represented by a circle in Figure 1A) was not straightforward. In clear contrast with MalK, the primary structure of OpuAA does not contain the fingerprint of the CUT1 (carbohydrate uptake transporter 1) subfamily represented by a characteristic GI/VRPE consensus sequence [34]. Rather the sequence indicates the presence of two CBS domains (Figure 1B) as evident by a sequence alignment of the accessory domain of OpuAA from *B. subtilis* with OpuAA from *L. lactis*, IMPDH (inosine-monophosphate dehydrogenase) and the orphan open reading frames from *Thermotoga maritima* and *Thermoplasma acidophilum* [25]. These open reading frames were chosen, because crystal structures of the CBS modules are available (see the Figure legends for the corresponding PDB entries). Among the four crystal structures, *T. acidophilum* TA0289 had the highest sequence similarity (51%) and was used for separate homology modelling. The resulting model of the isolated accessory domain of OpuAA is shown in Figure 1(C) displaying the characteristics of the tandem organization of CBS domains.

Since no prior information of the relative orientation of the accessory and the core NBD domain are available, no attempts were made to include the homology model of the CBS domain of OpuAA (Figure 1C) into the MalK-derived homology model of OpuAA (Figure 1A).

With the homology model at hand, we selected three residues of OpuAA within the catalytic and helical domains for changing to a cysteine residue. These residues are highlighted as spheres in Figure 1(A). Ser⁴⁵ is located in the catalytic domain at the C-terminal end of the OpuAA-specific insertion between β -strands 1 and 2. Gly¹⁶¹ is at the N-terminal end of the ABC-signature motif. Ser¹⁷¹, the conserved serine residue of the ABC-signature motif, was also selected for cysteine mutation to distinguish the composite dimer architecture from the one observed in the MalK crystal structure from *Thermococcus litoralis* [35], which shows a different arrangement of the two monomers in the NBD-dimer. Wild-type OpuAA and the three cysteine mutants were overexpressed in *E. coli* and purified as described in the Materials and methods section. Analysis of the two single cysteine mutants (S45C and G161C) under reducing and oxidizing conditions (see Supplementary Figure S1 at <http://www.BiochemJ.org/bj/412/bj4120233add.htm>) demonstrated that only negligible intermolecular disulfide bond formation occurred. More importantly for our conformational

Table 1 Kinetic parameters of monomeric OpuAA and the mutants used in the present studyATPase assays were performed in 10 mM sodium phosphate (pH 7.5) and 1 M NaCl as described in the Materials and methods section. Values are means \pm S.D. of two independent measurements.

Protein	K_m (mM)	k_{cat} (ATP/min)	Catalytic efficiency ($M^{-1} \cdot \text{min}^{-1}$)
OpuAA	0.6 ± 0.2	1.1 ± 0.1	1833
OpuAA S45C	0.7 ± 0.1	1.3 ± 0.1	1857
OpuAA G161C	2.8 ± 0.4	0.8 ± 0.1	285
OpuAA S171C	Not determined	0.08 ± 0.01	Not calculated
OpuAA F19W	1.7 ± 0.1	1.5 ± 0.1	882

analysis was the ATPase activity of the mutant proteins (Table 1). The wild-type enzyme hydrolysed ATP at a rate of $1.1 \pm 0.1 \text{ min}^{-1}$ under the conditions of the assay [11]. In contrast with the S45C and the G161C mutants, which hydrolysed ATP at comparable rates, the S171C mutant displayed hardly any turnover ($0.08 \pm 0.01 \text{ min}^{-1}$). Owing to this result, the S171C mutant was not used for further studies.

In order to use FRET quantitatively and to extract distance information, it is of importance to obtain a reliable value for the labelling efficiency [36]. The engineered single cysteine mutants of OpuAA allowed us to employ maleimide chemistry and covalently link the individual fluorophores, OG or TR. Surprisingly, labelling efficiencies were rather low (approx. 50% for the G161C and approx. 60% for the S45C mutant for both dyes). To exclude non-specific labelling due to the prolonged reaction time, wild-type OpuAA was treated with the fluorophores under similar conditions. Here, no labelling above background was detected after separating protein and fluorophore (results not shown). Additionally, attachment of the dyes changed their molar absorption coefficient as well as the absorption maximum (12 nm for TR and 8 nm for OR; Supplementary Figure S2). To account for the low labelling efficiency and the changes in the physical properties of the protein-attached fluorophores, we established a second purification step, anion-exchange chromatography, to separate labelled and non-labelled protein (Figure 2). A separation of a labelled and a non-labelled protein species is evident from the absorption properties shown in the representative chromatograms of OpuAA S45C-OG (Figure 2A), OpuAA S45C-TR (Figure 2B), OpuAA G161C-OG (Figure 2C) and OpuAA G161C-TR (Figure 2D).

To investigate further whether the apparent separation was indeed quantitative, we applied ESI-MS of the two fractions obtained by anion-exchange chromatography. ESI-MS analysis of fraction I, which eluted at lower ionic strength, revealed the presence of a single protein species with a molecular mass of 47174 Da (Figure 3A). The calculated average molecular mass of OpuAA S45C, including a C-terminal hexahistidine tag and a formylated methionine residue, is 47174.48 Da. The second fraction, which eluted at higher ionic strength, revealed the presence of a single protein species of 47657 Da in the case of OpuAA S45C-OG (Figure 3B) and 47921 Da in the case of OpuAA S45C-TR (Figure 3C). These mass differences correspond within experimental error of the MS measurements to the molecular masses of the individual fluorophores [differences of 483 Da for the sodium adduct of OG (expected 486.35 Da) and 747 Da for the sodium adduct of TR (expected 751.83 Da)].

A detailed analysis of the monomer-dimer equilibrium of OpuAA [11], has provided a toolbox to generate monomers or dimers of OpuAA depending on the protein concentration and ionic strength. This allowed us to prepare OpuAA-OG/OpuAA-TR pairs at a molar ratio of 1:9, which ensures that all (>95%) OG-labelled OpuAA molecules are indeed in an OG-TR dimer.

**Figure 2** Quantitative separation of labelled and non-labelled single cysteine mutants of OpuAA by anion-exchange chromatography

A (OD) at 216 nm (protein absorption) is shown as a solid line and A at 491 nm (OG absorption; A and C) and 591 nm (TR absorption; B and D) is shown as dotted lines respectively. The applied NaCl concentration gradient is shown as a dashed line in the indicated concentration range. (A) OpuAA S45C-OG, (B) OpuAA S45C-TR, (C) OpuAA G161C-OG and (D) OpuAA G161C-TR. For further details see the Materials and methods section.

On the other hand, a high molar excess of acceptor might result in an apparent increase in transfer efficiency due to radiation-dependent processes such as acceptor self-absorption.

Figure 3 High-resolution MS analysis of OpuAA (A), OpuAA S45C-OG (B) and OpuAA S45C-TR (C)

The arrow in (B) and (C) indicates the position of unlabelled OpuAA, which is below 2% according to an analysis of the peak area.

However, these processes depend solely on the concentration of the acceptor and a proper choice will eliminate this obstacle. Therefore we measured the fluorescence of a 50 nM sample of OpuAA-OG (donor) in the presence or absence of a 9-fold molar excess of TR-conjugated OpuAA (results not shown) under conditions that abolish FRET. Comparison of the two spectra clearly showed that marginal self-absorption of TR occurred. Consequently, we used a fixed donor concentration of 50 nM in all subsequent experiments.

A representative set of static FRET experiments is shown in Figure 4 for the OpuAA S45C-OG/OpuAA S45C-TR dimer in the nucleotide-free (Figure 4A), the ATP-bound (Figure 4B) and the ADP-bound (Figure 4C) states. The broken lines show the sum of two control experiments, OpuAA S45C-OG and wild-type OpuAA (molar ratio of 1:9) and wild-type OpuAA and OpuAA S45C-TR (molar ratio of 1:9), whereas the solid lines show the fluorescence spectrum of an OpuAA S45C-OG/OpuAA S45C-TR mixture (molar ratio of 1:9). The insets show the corresponding difference spectra. As is evident from these experiments, FRET can be detected for the nucleotide-free and the ATP-bound states of dimeric OpuAA, but not for the ADP-bound state. The FRET efficiencies were calculated to 34% and 39% for the nucleotide-free and ATP-bound state according to

Figure 4 Static FRET measurements of OpuAA S45C in the nucleotide-free (A), ATP-bound (B) and ADP-bound (C) states in the absence of Mg^{2+}

In all three panels, the broken line represents the sum of two individual FRET experiments, OpuAA S45C-OG/OpuAA wild-type (molar ratio of 1:9) and wild-type OpuAA/OpuAA S45C-TR (molar ratio 1:9). The solid line shows the actual FRET experiments of OpuAA S45C-OG/OpuAA S45C-TR (molar ratio of 1:9). Acceptor concentration was always kept at 50 nM, and the corresponding dimers were prepared as described in the Materials and methods section. The inset in each panel shows the difference spectra of the corresponding FRET experiments (OG and TR pairs). The buffer used was 10 mM sodium phosphate (pH 7.5), 0.1 mM EDTA and 1 M NaCl. a.u., absorbance units.

eqn (2). A summary of the FRET efficiencies determined for this and the other combinations is given in Table 2.

Distance determinations through static FRET experiments require an accurate knowledge of the protein concentration. In the present study, concentration determination was complicated by the fact that the molar absorption coefficients of the dyes changed upon covalent attachment to the protein (see Supplementary Figure S2). We determined protein concentrations as outlined in the Materials and methods section and incorporated the changed molar absorption coefficients determined under the experimental conditions, but any error in the determination would

Table 2 Summary of the static and time-resolved FRET experiments

The dimeric species of the indicated single cysteine mutants of OpuAA of the nucleotide-free and ATP-bound states and the monomeric species of the indicated single cysteine mutants of OpuAA in the ADP-bound state were analysed as described in the Materials and methods section in the absence of Mg^{2+} . The determined transfer efficiencies at 519 nm (donor emission maximum) or the static FRET experiments were translated in distances according to the Förster equation assuming a Förster radius of the OG/TR pair of 51 Å [30]. In the case of the time-resolved experiments, amplitudes and half times were calculated from the ADP/ Mg^{2+} -induced decay of the dimeric forms of labelled OpuAA mutants as described in the Materials and methods section.

Dimer species	Static FRET				ADP/ Mg^{2+}	Time-resolved FRET		
	Nucleotide free		ATP			Nucleotide-free		
	Transfer efficiency (%)	Distance (Å)	Transfer efficiency (%)	Distance (Å)		Half time (min)	Transfer efficiency (%)	Distance (Å)
S45C-S45C	34	57	39	55	No transfer	22 ± 0.3	33	59
S45C-G161C	47	52	79	41	No transfer	20.7 ± 0.1	47	52
G161C-G161C	49	51	65	46	No transfer	12.9 ± 0.1	49	51

**Figure 5 Time-resolved FRET experiments**

(A) Dimers of the nucleotide-free state were prepared as described in the Materials and methods section and were chased by the addition of 10 mM ADP/ Mg^{2+} . Fluorescence was measured at 519 nm in 5 s intervals. From bottom to top: dimeric OpuAA S45C-OG/OpuAA S45C-TR (dashed line), dimeric OpuAA G161C-OG/OpuAA S45C-TR (dotted line), dimeric OpuAA G161C-OG/OpuAA G161C-TR (dotted-dashed line) and monomeric OpuAA G161C-OG/OpuAA G161C-TR (solid line). Note that monomeric samples were measured at an approx. 4-fold higher concentration than the dimeric samples. Traces were analysed according to eqn (3). The buffer used was 10 mM sodium phosphate (pH 7.5), 0.1 mM EDTA and 1 M NaCl. (B) Time-resolved transfer efficiencies were calculated according to eqn (4) and extrapolated to $t = 0$ to determine the initial transfer efficiencies, which are summarized in Table 2. a.u., absorbance units.

drastically affect the FRET distances extracted from those measurements. Thus we also thought of establishing an experimental approach that was independent of a prior exact knowledge of protein concentration. Here, time-resolved changes in donor fluorescence of monomeric or dimeric OpuAA G161C-OG/OpuAA G161C-TR, dimeric OpuAA G161C-OG/OpuAA S45C-TR and dimeric OpuAA S45C-OG/OpuAA S45C-TR (Figure 5A) provided a tool to countercheck the distance information of the static FRET experiments and to validate these results. Nucleotide-free samples of the indicated combinations

**Figure 6 Time-resolved intrinsic tryptophan fluorescence of the OpuAA F19W mutant**

The nucleotide-free dimeric form of OpuAA was prepared as described for the wild-type ATPase and ADP (1 mM) was added at zero time in the absence of Mg^{2+} . Tryptophan fluorescence was monitored at 350 nm over the indicated time frame and evaluated as described in the Materials and methods section. The buffer used was 10 mM sodium phosphate (pH 7.5), 0.1 mM EDTA and 1 M NaCl.

were incubated with ADP/ Mg^{2+} , and fluorescence was measured over the indicated time frame. The observed donor fluorescence increased over time in a strictly mono-exponential fashion for all dimeric probes, although it remained constant for the monomeric probe. Thus the increase in donor fluorescence corresponds to dimer decay, and the decay reaction was evaluated according to eqn (3). This analysis provided the amplitudes and half times of dimer decay and could be used to calculate the transfer efficiency for the individual combinations according to eqn (4) by extrapolation of the data to $t = 0$ (Figure 5B). This extrapolation allowed us to extract the transfer efficiencies without prior knowledge of protein concentration or the exact starting time point of the experiment. A summary of the calculated values is given in Table 2. This demonstrates the agreement between transfer efficiencies determined by static and time-resolved FRET.

Additional support for the ADP-induced dimer decay comes from independent experiments using the F19W mutant of OpuAA (Figure 6). Phe¹⁹, which based on sequence comparisons is interacting with bound nucleotide via π - π stacking, was mutated to a tryptophan residue to use intrinsic tryptophan fluorescence quenching to monitor nucleotide association and dissociation similar to the approach employed for the isolated NBD of HlyB [37]. Kinetic parameters of this mutant are summarized in Table 1. As shown in Figure 6, chasing of dimeric nucleotide-free OpuAA with ADP resulted in a quenching of the detected tryptophan fluorescence. As analysed for the monomeric form of OpuAA, the observed fluorescence reduction

is due to nucleotide binding and π - π interaction of the adenine moiety of ADP or ATP and Trp¹⁹ (Supplementary Figure S3 at <http://www.BiochemJ.org/bj/412/bj4120233add.htm>). However, the determined half time of fluorescence decay (18 ± 4 min) is similar with the half times determined for the time-resolved fluorescence experiments within experimental error (Table 3).

Based on the FRET-derived distance information for the two homo-pairs (S45C/S45C and G161C/G161C) and the hetero-pair (S45C/G161C) in the nucleotide-free and ATP-bound state (Table 2), a molecular model was created using FRETsg as anchor points for a structural alignment in O [38]. Although the C α -C α distances obtained from the FRET studies of the homo-pairs [56.9 Å (45–45) and 51.3 Å (161–161)] agreed with the open conformation of MalK (59.9 Å and 51.9 Å respectively) [20], the distance of the S45C/G161C pair was approx. twice the distance measured in MalK (52.1 Å compared with 22.3 Å). Thus the open nucleotide-free dimer of MalK was adjusted accordingly. Here, one monomer was kept fixed while the other was treated as a rigid body. The resulting model for OpuAA satisfying all FRET-derived distance restraints is shown in Figure 7(A). The canonical part of each NBD monomer, composed of the catalytic and helical subdomains, is shown in yellow and light orange respectively, and the accessory domains are in grey. The Walker A and ABC-signature motifs are highlighted in blue and red respectively, whereas the C α trace of the amino acids, which were mutated to cysteine residues and labelled with the corresponding fluorophores, is coloured green (position 45) and dark grey (position 161). Thin broken lines indicate the distances between the labelled amino acids, which were calculated from the FRET measurements. Interestingly, the closest C α -C α distance between opposing Walker A and ABC-signature motifs are 17 and 20 Å respectively. These values agree with the distance determined for the corresponding C α atoms of the nucleotide-free open form of MalK (17 Å) from *E. coli* [20]. Thus it appears that the overall structure of the canonical part of the NBD is identical between OpuAA and MalK. However, the accessory domains are in a different orientation from that expected from the MalK structure. As a consequence, severe clashes occur between the canonical and accessory part of opposing OpuAA monomers (Figure 7A), indicating that the accessory domain has to adopt a different orientation. Furthermore, the D-loop motifs (SALD in OpuAA and SNLD in MalK) of opposing monomers are in close contact (C α -C α distance of 7 Å). As shown in Figure 7(B), structural superimposition reveals that one monomer of the OpuAA model aligns very well with a monomer of the nucleotide-free open structure of MalK [rmsd (root mean square deviation) of 1 Å over 381 C α atoms]. The two monomers of MalK are coloured magenta and cyan and the Walker A and ABC-signature motifs in blue and red respectively. In clear contrast, the second monomer displayed a translational movement of 9.5 Å as calculated for the conserved lysine residue of the Walker A motifs, which are shown as blue ribbons (Lys⁴² in MalK and Lys⁷² in OpuAA). As a consequence, the accessory domain of the second monomer of the OpuAA model (light grey) is displaced compared with the MalK structure (light magenta). A structural superimposition of the OpuAA model and the nucleotide-free semi-open form of MalK [20] revealed that one monomer imposes slightly less accurately with OpuAA (rmsd of 1.9 Å over 336 C α atoms; results not shown). The C α -C α distance of opposing Walker A and ABC-signature motifs is also shorter (13 Å) than in the FRET-derived model of OpuAA (17 and 20 Å respectively).

Following the same strategy as outlined for the nucleotide-free state of OpuAA, a model was derived for the ATP-bound dimeric state (Figure 8A) that satisfied the distance restraints derived from

Figure 7 Stereo view of the FRET-derived homology model of nucleotide-free OpuAA

(A) The accessory domains are shown in white, whereas the canonical NBDs are given in yellow and light orange respectively. Note that the accessory domain of MalK was used in the homology modelling because proper location of the CBS domain, which is shown in Figure 1(C), is not possible. FRET-derived distances between amino acid residues 45 (green) and 161 (dark grey) are highlighted by black broken lines. The individual distances are given in Table 2. The Walker A motif is highlighted in blue and the ABC-signature motif in red. (B) Stereo view of a structural superimposition of the FRET-derived homology model of OpuAA and the open conformation of the nucleotide-free form of MalK (PDB entry: 1Q1E). Colour-coding of OpuAA is as in (A). Individual chains of MalK are shown in magenta and cyan, whereas the Walker A and ABC-signature motifs are highlighted in blue and red respectively. For structural superimpositions, the Walker A and B motifs were used. After improvement of the superimposition, the rmsd between monomer A of OpuAA and MalK was 1 Å over 381 C α atoms.

FRET measurements in solution (Table 2). Here, the C α -C α distance between opposing Walker A and ABC-signature motifs shortens to 13 Å compared with the model of the nucleotide-free state. Furthermore, a superposition of the nucleotide-free and the ATP-bound state of the OpuAA model (Figure 8B) revealed that the canonical part of the NBD, coloured cyan and magenta, undergoes an induced fit upon ATP-binding, i.e. a rigid-body motion of the helical domain towards the catalytic domain.

DISCUSSION

The large body of biochemical data [39] and the crystal structures of MalK [20,21], the isolated NBD of the maltose transporter, combined with the recently published crystal structure of the full-length transporter [18], has provided a molecular picture of how substrate import is catalysed by this ABC importer. Thus a 'tweezers-like' motion was proposed for MalK. In this model, the additional domains of MalK form the bottom of the tweezers, keeping two MalK monomers together during the catalytic cycle, while the catalytic and helical domains of the MalK monomers undergo nucleotide-dependent association and dissociation reactions. A similar monomer-dimer equilibrium

Figure 8 Stereo view of the FRET-derived homology model of OpuAA in the ATP-bound state

(A) ATP, which should be located between the Walker A (blue) and ABC signature (red) motifs of opposing monomers is not included in the model, because no structural knowledge of the exact position exists. The accessory domains, which adopt the structure of the MalK model, are depicted in white. The canonical NBDs are shown in cyan and magenta respectively. The anchors points (Ser⁴⁵ and Gly¹⁶¹), which were used in the FRET studies, are highlighted in green and black respectively and their distances are indicated by broken black lines (exact values are given in Table 2). (B) Stereo view of the structural superimposition of the FRET-derived homology models of OpuAA in the ATP-bound state (cyan and magenta) and the nucleotide-free state (yellow and light orange). Colour-coding of the conserved motifs is as in (A).

was observed for OpuAA from *B. subtilis* [11]. However, in contrast with MalK, dimeric OpuAA was only observed in the absence of nucleotides or the presence of ATP, although it remained monomeric in the presence of ADP. Moreover, dimeric OpuAA could be converted into the monomeric form in the presence of excess ADP. Such an ADP-induced monomerization of OpuAA, but not of MalK, might be due to differences in the accessory domains. In contrast with MalK, the primary structure of OpuAA indicates the presence of two CBS domains arranged in tandem (Figure 1). CBS domains are found, for example, in voltage-gated chloride channels [40] or IMPDHs [41] and are thought to bind small molecules containing an adenosyl moiety such as AMP, thereby regulating enzyme activity [42,43]. However, ATPase assays of OpuAA in the presence of AMP had no effect on activity and the stoichiometry of ATP (results not shown and [11]). This suggests that the CBS domains of OpuAA do not interact with AMP in a functionally relevant manner. Nevertheless, the core domain of MalK (catalytic and helical domain) is of sufficient homology (36% identity and 69% homology) with OpuAA to allow homology modelling (Figure 1), while a homology model of the accessory domain of OpuAA was constructed based on its closest structurally known homologue, TA0289 (Figure 1C). Based on this model, three amino acids were chosen and converted

into cysteine residues (S45C, G161C and S171C) for subsequent fluorophore labelling.

Wild-type and the three mutant proteins could be overexpressed and purified to homogeneity (Supplementary Figure S1). As summarized in Table 1, turnover rates for the wild-type enzyme and the S45C and G161C mutants were identical within experimental error. Also the K_m values for the wild-type enzyme and the S45C were identical, whereas the K_m value for the G161C mutant increased by a factor of 5. The result is somewhat surprising since Gly¹⁶¹ is a surface-exposed residue and the structural model provides no explanation for this result. Since all subsequent experiments were performed under ATP-saturating conditions, these changes in K_m do not influence the results. In clear contrast, the S171C showed no ATPase activity and was not used in the following analysis.

Comparing this activity with the *in vivo* activity is not possible, because there exist no data on the number of transporters per cell [44]. However, assuming an activity typical for ATP transporters (approx. 1 ATP/s), indicates that the activity of the isolated NBD *in vitro* is 60 times lower than expected. But already in detergent solution, a 10-fold increase of the ATPase activity was observed in the presence of the TMD and the substrate-loaded SBP [9]. This clearly suggests that a properly assembled transporter requires higher activity than displayed by the isolated NBD. However, the results of the re-assembly studies in detergent solution [9] support the notion that the isolated NBD is properly folded and adopts a transport-competent state that can be stimulated in a SBP- and substrate-dependent manner.

The S45C and S161C were labelled employing two thiol-specific maleimide fluorophores, OG and TR. The use of TR and OG, an efficient FRET pair [30] with a Förster radius of 51 Å, should in principle allow us to extract distance information in the different functional states of the isolated NBD, i.e. nucleotide-free, ATP- and ADP-bound. However, labelling efficiencies were at best 60%, a result that cannot be explained based on the homology model, because the two residues chosen are surface-exposed. Instead of trying to optimize labelling efficiency, we developed an additional purification step to separate labelled and non-labelled species (Figure 2). Although the ion-exchange chromatogram indicated quantitative separation, we further analysed the identity and homogeneity of the two fractions obtained after ion-exchange chromatography by ESI-MS (Figure 3). Importantly, the amount of non-labelled OpuAA as indicated by an arrow in Figures 3(B) and 3(C) was below 2% as calculated from the peak areas of the ESI-MS spectra of OpuAA S45C-OG and OpuAA S45C-TR respectively. These two independent sets of experimental evidence demonstrate a quantitative separation of labelled and non-labelled OpuAA, which is a prerequisite for subsequent quantitative FRET measurements.

A process to assemble and de-assemble homodimers of OpuAA has already been described in detail [11] and was readily applied to the labelled single cysteine mutants. However, FRET efficiency strongly depends on a complete donor-acceptor pairing [30]. Statistical mixing of a 1:1 mixture of OG- and TR-labelled OpuAA would in theory result in the formation of 25% dimers composed of donors only (OG/OG), 25% dimers composed of acceptors only (TR/TR) and 50% composed of donor and acceptor (OG/TR). Although such statistical mixing has been verified experimentally for other isolated ABC-NBDs [37,45,46], and additionally a mathematical treatment to correct incomplete assembly is possible in principle, the dynamic monomer-dimer equilibrium of OpuAA would further complicate the evaluation. Therefore we decided to use a molar ratio of donor/acceptor of

1:9 to ensure quantitative 'pairing' of OpuAA–OG with OpuAA–TR. Under these conditions, FRET could be observed for the 45–45, 45–161 and 161–161 pairs in the nucleotide-free and ATP-bound state, but not in the ADP-bound state (Figure 4). Transfer efficiencies are summarized in Table 2. In the light of the biochemical characterization of the isolated NBD of the OpuA transporter [11], these results demonstrate that a dimer is present in the nucleotide-free and ATP-bound state respectively, whereas the protein is monomeric in the ADP-bound state. However, one has to realize that a determination of transfer efficiencies relies on an accurate protein concentration determination. Since the molar absorption coefficient of the dyes changed upon coupling (Supplementary Figure S2), protein concentration determination might become unreliable. To overcome, this problem, we also performed time-resolved FRET experiments (Figure 5). In this case, the decay in FRET signal of nucleotide-free or ATP-bound dimeric OpuAA samples was measured over time in the presence of 10 mM ADP, which induces dimer dissociation. From the determined amplitudes and the half time of dimer decay, transfer efficiencies could be calculated in a protein-concentration-independent way (Table 2). The agreement between these values and the values determined from the static measurements (Table 2) suggests that the distances, which can be derived from the transfer efficiencies, can be used as distance restraints for modelling the dimeric state of OpuAA.

Similarly to the HlyB system, the introduction of a tryptophan residue at position 19 of OpuAA lowered the catalytic efficiency of the enzyme 2-fold (Table 1). However, in our assays, saturating ligand concentrations were used and, more importantly, hydrolysis was prevented by adding EDTA to the buffer so that the enzymatic activity is not as important and the 2-fold reduction can be tolerated. Thus the chase of the nucleotide-free dimer of OpuAA F19W with ADP or ADP/Mg²⁺ displays the same result, as the ADP-induced dissociation of the OpuAA dimer detected by fluorescence, but FRET experiments report changes in distance, i.e. dimer decay directly, the F19W mutant uses nucleotide association/dissociation as the read-out. However, one has to keep in mind that the k_{cat} value of ATPase activity under these conditions is approx. 1 min⁻¹ (Table 1 and [11]), whereas the half time of dimer decay was between 12.9 ± 0.1 and 22 ± 0.3 min. Stopped-flow experiments employing changes of the intrinsic tryptophan signal (results not shown) revealed that nucleotide association was faster than the time resolution of the experiment (approx. 1 ms). Thus ATPase activity is either limited by hydrolysis as suggested for the HlyB–NBD [28] or the dissociation of the dimer as suggested for MJ1276 [27]. The current model of ATP hydrolysis within ABC domains assumes that dimer decay occurs every time the two ATPs bound to the composite dimer are hydrolysed. Such a scenario is hard to imagine for OpuAA, because a k_{cat} of 1 min⁻¹ and the half time of dimer decay (between 12 and 22 min) are not compatible with this model. However, Gadsby and co-workers [47] have demonstrated that, in CFTR (cystic fibrosis transmembrane conductance regulator), repetitive cycles of ATP hydrolysis can occur before the dimer decays. Clearly, in CFTR the NBD composite sites are unequal, because the degeneration of certain residues critical for catalysis generates one ATP-binding site with no or only little ATP activity, whereas the other site contains the canonical residues and is capable of hydrolysing ATP. Although OpuAA does not contain an asymmetrical ATP-binding site, it is tempting to speculate that the 10–20-fold difference between ATP turnover and dimer decay is due to a similar phenomena. ATP hydrolysis and dimer decay are not strictly coupled, and repetitive cycles can occur in both binding sites before the dimer dissociates. Dimer decay on the other hand would finally terminate ATPase activity. That

would also suggest that a single ATP hydrolysis event and the overall termination of activity (dimer decay) might have different rate-limiting steps. However, this hypothesis requires further verification, and, although appealing, the differences between CFTR and OpuAA in sequence and the resulting functional consequences are obvious, therefore further experimental analysis is necessary before the discrepancy between turnover and dimer decay can be resolved.

Based on the distance restraints derived from the static and time-resolved FRET measurements (Table 2), the dimeric homology models of OpuAA (nucleotide-free and ATP-bound) that were based on the dimeric crystal structures of MalK, were modified to satisfy the restraints (Figures 7 and 8). As shown, in Figures 7(A) and 8(A), the FRET-derived distances can only be incorporated into the homology models if the accessory domains are not in close contact in OpuAA as they are in MalK. Furthermore, the catalytic and helical domains in the second monomer are translationally shifted by 9 Å if comparing MalK with OpuAA (Figure 7B). This excludes that a simple rotation of the linker between core NBD and the CBS-containing accessory domain is sufficient to generate a 'MalK-like' arrangement. However, one has to stress that the accessory domain of the OpuAA model shown in the present study contains the MalK-fold, whereas sequence analysis clearly revealed the presence of CBS domains in OpuAA that adopt a fold similar to the one shown in Figure 1(C). The low structural homology between these two folds prohibited any further homology modelling. Analysis of the buried surface area of the OpuAA model revealed a value of 130 Å² compared with 1900 Å² in the ATP-bound state of MalK [20]. Clearly, the calculated value of the buried surface area is too small to explain the dimeric nature of nucleotide-free OpuAA in solution [11]. However, the accessory domains, as shown in Figure 7(A), do not have any contact, so the only stabilization is provided by interactions of the canonical part (helical and catalytic domain) of OpuAA. Thus the FRET-derived model strongly suggests that the CBS-containing accessory domains stabilize the dimeric nature of this ATPase subunit, but that the relative orientation of canonical NBD and the accessory domain is different in OpuAA and MalK. This finding is similar to the situation observed in the crystal structure of CysA [48], the NBD of a putative sulfate-import system. In this case, the orientation of the accessory domain in one of the two dimers is also different from that of MalK and suggests that the relative three-dimensional orientation of the core NBD and the accessory domain is different in different NBDs and might be a consequence of functional requirements imposed on the transporter (nature of substrate, interacting molecules/proteins, etc.). On the other hand, a rigid-body inward motion is observed for the helical domain of the ATP-bound model compared with the nucleotide-free state (Figure 8B). This rigid-body motion of induced fit upon ATP-binding was first proposed for MJ1276 [49] and subsequently verified in the crystal structures of other isolated NBDs in the ATP-bound state [20,27–29]. Here, the inward motion ranged from 16° to 25°. In our model, the helical domain of the nucleotide-free state (coloured yellow and light orange in Figure 8B) undergoes an inward motion of approx. 17°. This demonstrates that the basic motion in the core NBD is also preserved in OpuAA.

In summary, although the orientation of the accessory domain is not identical in OpuAA and MalK, the basic principles of structural changes occurring within the helical domain upon ATP-binding that have been elaborated for many systems are also conserved in OpuAA. It is also tempting to speculate that the OpuAA dimer adopts the open conformation of MalK in solution in the absence of nucleotides and not the semi-open state, but with a different arrangement of the accessory domain

that very probably stabilizes the dimer and also performs a tweezer-like function as it was proposed for MalK [20]. Further studies, such as additional FRET or cysteine-based cross-linking experiments, are necessary to determine the exact orientation of the CBS domains to each other, but a definitive answer will only become available upon determining the three-dimensional crystal structure of OpuAA in different functional states. However, in the light of the proposed role of this module in regulating transport function, it is important to realize that not only the primary structure, but also the quaternary arrangement is important for *in vivo* function.

We thank Suman Lata, Jacob Piehler and all members of the Institute of Biochemistry for the stimulating discussions and Robert Tampé for constant support and encouragement. We are grateful to Filip Oesterhelt, Claus Seidel and Sander Smits for many insightful discussions concerning the FRET experiments and their interpretations. This work was supported by the DFG (special priority programme 1070, grants BR 796/51 to E. B. and Schm1279/4-1 to L. S.).

Figure S1 Purification of wild-type and single cysteine mutants of OpuAA

Left-hand panel: Coomassie-Blue-stained SDS/PAGE (15% gel) of OpuAA wild-type, S45C and G161C. Right-hand panel: Coomassie-Blue-stained SDS/PAGE (15% gel) under reducing (Red.) and oxidizing (Oxid.) conditions of OpuAA S45C and G161C. Molecular masses in kDa of the marker proteins are given on the left-hand side of each panel.

Figure S2 Absorption spectra of identical concentrations of OG (A) and TR (B) in buffer [10 mM sodium phosphate (pH 7.5) and 1 M NaCl; black lines] and after covalent attachment to OpuAA [10 mM sodium phosphate (pH 7.5) and 1 M NaCl; blue lines]

The vertical broken lines indicate the change in the absorption maxima. As depicted, the absorption coefficient at the absorption maxima increased 2-fold for TR but decreased 1.2-fold for OG after the labelling reaction. a.u., absorbance unit.

Figure S3 Nucleotide-induced tryptophan-quenching of the F19W OpuAA mutant

Data were recorded as described in the Materials and methods section of the main text at $20 \pm 1^\circ\text{C}$ in 10 mM sodium phosphate (pH 7.5), 1 M NaCl and 2 mM Mg^{2+} using monomeric OpuAA. Data were analysed using a 1:1 Langmuir binding isotherm and K_d values were calculated to be $215 \pm 9 \mu\text{M}$ (ATP/ Mg^{2+}) and $30 \pm 0.4 \mu\text{M}$ (ADP/ Mg^{2+}). The control AMP/ Mg^{2+} , shows the specificity of the binding reaction. This specificity clearly demonstrates the involvement of residue 19 of OpuAA in nucleotide binding.

Abstract

Bacillus subtilis synthesizes the compatible solute glycine betaine from an exogenous supply of the precursor choline as an osmoprotectant. Import of choline is mediated by two osmotically inducible ABC-transport systems, OpuB and OpuC. OpuB is specific for choline, whereas OpuC mediates the import of various osmoprotectants. OpuBC is the substrate binding protein of the OpuB transporter and we have analyzed the affinity of the OpuBC/choline complex by intrinsic tryptophan fluorescence (K_d approximately 30 μM). The X-ray crystal structure of the OpuBC/choline complex revealed a fold typical for class II substrate-binding proteins with the ligand trapped in a deep cleft formed by the two domains of OpuBC. The positively charged trimethylammonium head-group of choline is wedged into an aromatic cage formed by four tyrosine residues and is bound via cation- π interactions. The alcohol group of choline protrudes from this aromatic cage and makes a single direct interaction with Gln-19. The substitution of this residue by Ala decreases choline binding-affinity by approximately 15-fold. A water network stabilizes choline within its substrate-binding site and promotes indirect interactions between the two lobes of OpuBC. Disruption of this intricate water network by site directed mutagenesis of selected residues in OpuBC either strongly reduces choline-binding affinity (between 18-fold and 25-fold), or abrogates ligand binding altogether. A comparison of the OpuBC/choline structure with the crystal structure of the glycine betaine binding protein ProX from *Archaeoglobus fulgidus* revealed why glycine betaine cannot be bound stably by OpuBC despite the fact that the trimethylammonium head group of this ligand would fit correctly into the aromatic cage of OpuBC.

Introduction

Changes in the osmotic conditions of the environment are key factors that influence growth and survival of microorganisms in their varied ecological niches (1). Since most microorganisms possess a turgor, an intracellular hydrostatic pressure considered to be essential for cell expansion (2). Increases or decreases in the external osmolarity inevitably trigger osmotically driven water fluxes across the semi-permeable cytoplasmic membrane. The direction and magnitude of these water fluxes is determined by the differential in the osmotic potential between the interior of the cell and the surrounding (3, 4).

The slowing of cell growth and the eventual growth arrest under severe high osmolarity conditions is correlated with the diminished content of free water in the bacterial cell (5). To counteract the efflux of water and to promote a physiologically adequate level of hydration and turgor, microorganisms initiate a cellular adjustment process that aims at an increase in the osmotic potential of the cytoplasm through the amassing of water-attracting solutes (3, 4). In many microorganisms, this is typically a multiphasic process in which potassium ions are initially imported as an immediate stress reaction. This initial phase is then followed by the amassing of a selected class of organic osmolytes, the compatible solutes, for a sustained adjustment to high osmolarity surroundings (1-4). The accumulation of compatible solutes allows the cell to export the initially imported potassium ions and thereby reduce the ionic strength of the cytoplasm without compromising its osmotic potential (6).

Compatible solutes possess special biophysical and biochemical properties that make them highly congruous with cellular functions so that cells can amass them to exceedingly high levels (7, 8). These organic osmolytes have been selected in the course of evolution as effective cytoprotectants not only by members of the *Archaea* and *Bacteria* but also by *Eukarya* (1, 9, 10). Microbial cells accumulate compatible solutes either through synthesis or uptake for environmental resources (3, 4, 11, 12). Glycine betaine, a tri-methylated derivative of the amino acid glycine, is without any doubt the most widely used compatible solute in nature (1, 9, 10, 13). Most microbes that have been studied in the context of their adaptation to high osmolarity environments have been found to possess osmotically stimulated high-affinity uptake systems for glycine betaine (2-4, 11, 12).

Frequently, microorganisms can also synthesize glycine betaine and they can do so either *via de novo* synthesis or by oxidizing the precursor choline. The *de novo* synthesis of glycine betaine is accomplished by a step-wise methylation of the amino acid glycine with *S*-adenosylmethionine as the methyl donor (14). This enzymatic process is energetically very expensive due to the required regeneration of the *S*-adenosylmethionine cofactor (14). Consequently, most microorganisms synthesize glycine betaine by oxidizing choline, an energetically more favorable process. For this latter biosynthetic route, choline is first imported from the environment through osmotically inducible transporters and this precursor can then be converted into glycine betaine by a combination of various enzymes (15-18). It should be

noted in this context, that choline has no osmoprotective property *per se* in microorganisms (19).

Glycine betaine plays a key role in the defense of the soil-dwelling Gram-positive bacterium *Bacillus subtilis* against high osmolarity challenges that are caused by the drying of the upper layers of the soil (20). *B. subtilis* possesses three high-affinity uptake systems for this osmoprotectant: the ABC-transporters OpuA and OpuC and the BCCT-type transporter OpuD (Fig. 1)(21-23). The expression of the structural genes for these transport systems is up-regulated in high-salinity stressed *B. subtilis* cells (24, 25), thereby providing more glycine betaine transport capacity to the cell under osmotic stress conditions (21, 22). Glycine betaine can also be synthesized by *B. subtilis* from the precursor choline (19). For this purpose, choline is imported with high affinity through the substrate-specific OpuB ABC-transporter and the promiscuous ABC-transporter OpuC (Fig. 1)(20, 23). The imported choline is then oxidized to glycine betaine by the concerted actions of the alcohol dehydrogenase GbsB and the glycine betaine aldehyde dehydrogenase GbsA (Fig. 1)(15). The choline to glycine betaine biosynthetic pathway provides *B. subtilis* with a considerable degree of osmotic tolerance (19, 23).

Where does the choline for glycine betaine synthesis come from in the main natural habit of *B. subtilis*, the soil? Choline is an important component of the eukaryotic cell membrane and hydrolytic enzymes released by microorganisms liberate the choline moiety from lipids of decaying cells, primarily from rotting plant material (19, 26). Since the choline content of the soil is very low and variable (26), high affinity uptake systems are required to effectively scavenge it. The kinetic parameters of the *B. subtilis* OpuB and OpuC transporters with K_m -values in the low μM range, make these two ABC systems suitable for such a task (23).

The structural genes for the OpuB and OpuC ABC importers are located only a few kilo-base pairs apart on the *B. subtilis* genome and the high degree of amino acid sequence identity of their components (up to 70 % in the SBPs) suggests that these uptake systems have evolved from a gene duplication event (23). The OpuB transporter is highly specific for the uptake of choline, whereas OpuC not only imports choline but also various other compatible solutes (Fig. 1)(20). Gene duplication events are an important driving force in microbial evolution since they generate gene copies onto which adaptive evolution can act without impairing the physiological function of the original gene (27). Hence, a possible scenario that can be envisioned is the initial presence of the substrate-specific OpuB choline uptake system that worked in conjunction with the GbsA and GbsB glycine betaine biosynthetic enzymes (Fig. 1). The *opuB* operon was then duplicated and the resulting second copy of the transporter subsequently evolved into an uptake system with a broad substrate specificity, OpuC. In this way, the spectrum of compatible solutes that could be used by *B. subtilis* cells as osmoprotectants was significantly expanded (Fig. 1)(20) since some of the known osmoprotectants of *B. subtilis* (e.g. L-carnitine, choline-O-sulfate, ectoine) enter the cell exclusively via the OpuC transporter (28-30).

If the above described scenario for the evolution of the *B. subtilis* OpuB and OpuC transporters is correct, then the question arises what are the structural determinants of the OpuB and OpuC ABC transport systems that govern their substrate specificity? It is the generally accepted view that the substrate specificity of a given microbial binding-protein-dependent ABC transporter is primarily determined by the substrate specificity of the cognate ligand binding protein (31, 32). However, it is known from the genetic and structural analysis of the maltose/maltodextrin ABC transporter from *Escherichia coli*, that a low-affinity substrate binding site is present in one (MalF) of the two permease components (MalF and MalG) of the transporter and that this binding site contributes significantly to substrate import and specificity (33-35).

Since *B. subtilis* is amenable to sophisticated genetic techniques, the sequence-related OpuB and OpuC transporters are attractive model systems to study the evolution of the substrate specificity of microbial binding-protein-dependent ABC transporters. The substrate binding proteins (OpuBC and OpuCC) of the OpuB and OpuC ABC transporters are lipoproteins that are tethered on the outer surface of the cytoplasmic membrane of *B. subtilis* (Fig. 1)(23). The amino acid sequence of the OpuBC and OpuCC proteins are 25 % identical, but judging from the substrate profile of their cognate transporters (Fig. 1), their substrate specificity must be very different.

To further characterize the OpuB and OpuC ABC transport systems, we report here a high-resolution crystal structure of the OpuBC ligand binding protein in complex with its natural ligand choline. This crystal structure does not only reveal the molecular determinants for high-affinity choline binding by OpuBC but it also provides a rational explanation why glycine betaine, a substrate for the OpuC transporter but not for the OpuB system (Fig. 1), cannot be stably bound by the OpuBC ligand binding protein.

Results and Discussion

Purification and functional characterization of the *B. subtilis* OpuBC protein

The OpuBC protein is initially synthesized in *B. subtilis* as a precursor protein with a 22 amino acid long signal sequence to direct its export across the cytoplasmic membrane. During protein translocation, the OpuBC signal sequence is proteolytically removed by a signal sequence-specific peptidase and the newly formed mature N-terminus of the OpuBC protein (Cys-23) is lipid modified (Fig. 1)(23). We constructed an expression system for the *opuBC* gene that allowed the recombinant production of the *B. subtilis* OpuBC protein in *E. coli* and its purification via *Strep-tag-II* affinity chromatography. The OpuBC protein used for the subsequent biochemical and crystallization experiments (Fig 2A) did not possess the originally present *Strep-Tag-II* affinity peptide but it carried a Gly residue (instead of Cys-23) at its N-terminus (see Materials and Methods) in order to prevent its lipid modification.

Substrate-binding activity of OpuBC

The OpuBC protein contains three Trp and 17 Tyr residues spread throughout its amino acid sequence. Using the intrinsic Trp/Tyr fluorescence of the purified OpuBC protein, we measured an emission spectrum between 290 and 400 nm and detected a maximum of fluorescence emission at about 340 nm (Fig 2B). The addition of 100 μ M choline, the physiological substrate of the OpuB transporter (23) to the OpuBC protein solution led to an increase in the intensity of the intrinsic fluorescence (Fig 2B), consistent with the expected binding of choline to the OpuBC solute receptor. In contrast, the addition of 1 mM glycine betaine to the OpuBC protein solution did not trigger such a change in the fluorescence intensity (data not shown). Since the properties of ligand-binding proteins typically determine the substrate specificity of a given microbial ABC importer (31, 32) the recombinantly produced OpuBC protein exhibited a substrate-binding specificity for choline expected from previously reported osmoprotection assays and transport experiments conducted with intact *B. subtilis* cells (23).

Equilibrium binding experiments of OpuBC with its ligand choline

The change in the intrinsic Trp/Tyr fluorescence of OpuBC observed after addition of choline to the purified protein (Fig 2B) was used to determine the dissociation constant for the OpuBC:choline complex. For these experiments, we kept the OpuBC concentration constant (1 μ M) and varied the choline concentration from 1 μ M to 200 μ M. From the resulting spectroscopic data we calculated a K_D value for choline of 30.5 ± 3.2 μ M (Fig 2C). This K_D value is very similar to that for the OpuAC:glycine betaine complex (approximately 20 μ M) determined by the same method for the OpuAC ligand binding protein (Fig 1) from the *B. subtilis* OpuA ABC-transport system (36, 37).

Crystal structure of OpuBC from *Bacillus subtilis* in complex with choline

As noted previously by Schiefner *et al.* (38), the amino acid sequence of the *B. subtilis* choline-binding protein OpuBC is related (29 % and 48 % amino acid sequence identity and similarity, respectively) to the glycine betaine binding protein ProX from the hyperthermophilic archaeon *Archaeoglobus fulgidus* (Fig 5). In particular, four Tyr residues that are part of the glycine betaine ligand-binding site of ProX (38) are conserved in the amino acid sequences of the OpuBC protein (Fig 4).

We took advantage of the available 2.1 Å crystal structure of the ProX:glycine betaine complex (38) to solve the crystal structure of the *B. subtilis* OpuBC solute receptor in complex with choline by molecular replacement. Crystals of the OpuBC protein were grown in the presence of choline and a native data set of the OpuBC:choline complex was collected at beamline ID-23 (ESRF, Grenoble) and scaled using XDS (39). Initial phases were obtained by molecular replacement using the program PHASER (40) with the crystal structure of ProX from *A. fulgidus* as a template (PDB entry: 1SW2)(38). The final structure was refined to a resolution of 2.0 Å, which allowed the modeling of water molecules. Data and refinement statistics as well as model content are summarized in Table 1.

The OpuBC protein was crystallized in the presence of choline and yielded a closed ligand bound conformation. The overall structure of the OpuBC:choline complex is depicted in Figure 3A. It shows the typical bi-lobal fold of a ligand binding protein functioning in the context of bacterial binding-protein-dependent ABC-importers (31, 32, 41). The OpuBC protein possesses two globular domains that are connected by two loops. A single choline molecule is trapped in a deep cleft formed by the two domains of the OpuBC protein, a location of the ligand that is characteristic for microbial substrate-binding proteins (41). Domain I of the OpuBC protein comprise residue 4 - 107 and 213 - 275 (depicted in dark gray) and domain II consists of residues 108 - 212 (depicted in orange) (Fig 3A). The two domains are formed by two central five stranded beta-sheets flanked by several alpha-helices. Residues 104 - 108 and 212 - 215 form the two hinge regions connecting both domains of OpuBC. When one compares domain I with domain II of the OpuBC protein, it becomes apparent that the latter domain is not only smaller in size but also exhibits differences in secondary structure (Fig 3A).

We found that the *B. subtilis* OpuBC protein belongs to cluster F-III of the newly developed crystal structure-based classification scheme for substrate binding proteins (SBPs)(41). Cluster F solely contains class II SBPs, binding proteins that possess two hinge regions connecting the two domains of the SBP. A characteristic feature of the binding proteins grouped into cluster F-III is the presence of a long hinge segment that in all likelihood permits a more flexible domain movement between the substrate-free (open) and substrate-bound (closed) conformations (41). In the OpuBC protein, this longer hinge segment comprises 10 residues and extends from Gln216 to Ser224; an additional, but shorter hinge region, spans from Asp114 to Tyr117 (Fig 3A). Although the OpuBC and AfProX proteins exhibit

only a modest degree of amino acid sequence identity (29 %) (Fig 5), an overlay of the OpuBC:choline crystal complex with that of the ProX:glycine betaine crystal complex reveals a high degree of similarity that is reflected in the RMSD between both crystal structures of 2.8 Å for 206 C-alpha atoms. The overall fold of the OpuBC protein from the mesophile *B. subtilis* (optimal growth temperature 37° C) and the AfProX protein from the hyperthermophile *A. fulgidus* (optimal growth temperature 83° C) is basically the same with only a few minor exceptions in some of the outer loop regions (data not shown).

The SBPs grouped into cluster F-III not only have a very similar overall structure, but they also possess ligand-binding sites with similar architectures (41). The current functionally characterized members of cluster F-III are the glycine betaine/proline betaine binding proteins ProX from *E. coli* (42) and *A. fulgidus* (38) the OpuAC glycine betaine/proline betaine binding proteins from *B. subtilis* (36, 37) and *Lactococcus lactis* (43) and the choline/acetylcholine binding protein ChoX from *Sinorhizobium meliloti* (44). The ligands of these solute receptors all possess bulky, positively charged trimethyl- or dimethylammonium headgroups that are positioned and held within the ligand binding site via cation- π interactions (45) with aromatic amino acid side chains forming a hydrophobic cage of varying geometries. As described below, the architecture of the substrate-binding site of OpuBC and the coordination of the choline ligand within the binding site conforms to the features established for all members of cluster F-III of the structure-based binding protein classification scheme (41).

Architecture of the choline-binding site in OpuBC

The ligand for the OpuBC protein, choline, is trapped deep in the cleft formed by the two lobes of the OpuBC protein (Fig 3A). A closer inspection of the ligand-binding site revealed that residues originating from both domain I and from domain II (Fig 3A) are used to form part of the choline binding site: the side chains of Tyr-71 and Tyr-221 (both contributed by domain I) and of Tyr117 and Tyr-197 (both contributed by domain II) together form an aromatic cage (Fig 3B). This aromatic cage accommodates and coordinates the positively charged trimethylammonium moiety of choline. Within the positively charged head group of choline, the charge is not fixed on the nitrogen atom of the choline molecule but is instead delocalized over the three methyl groups thereby forming a bulky cation. The binding of this cation is established by interactions with the aromatic side chains of Tyr-71, Tyr-117, Tyr-197 and Tyr-221 via cation- π interactions as was previously found in ligand binding proteins for the compatible solutes glycine betaine and proline betaine from *E. coli* (42), *B. subtilis* (37), *L. lactis* (43) and *A. fulgidus* (38) and in the choline/acetylcholine binding protein ChoX from *S. meliloti* (44). Distances between the carbon atom in the methyl groups of the choline head group and the four aromatic Tyr side chains within the substrate binding site of OpuBC are in the range of ~3.5 Å, consistent with the van der Waals radii of these atoms. In addition to these cation- π interactions, the trimethylammonium head group of choline forms hydrogen

bonds with Asn-115 side chain and backbone, respectively. The hydroxyl tail of choline protrudes from the aromatic cage and possesses only a single strong direct interaction with the OpuBC protein. The alcohol function of choline is coordinated by Gln-19 a residue that originates from domain I of OpuBC and has a distance of 2.7 Å to the choline ligand (Fig 3B).

In addition to the ligand choline that interacts with residues originating from both domains of the OpuBC protein (Fig 3B), a domain-domain interaction is observed between residues Asp-74 and Tyr-117 that is mediated via a water molecule depicted in blue spheres in Figure 3B. This water-mediated interaction between the two lobes of OpuBC is further stabilized via the interactions of an additional water molecule with Leu-155. Via these two water molecules, Leu-155 (located in domain II) interacts indirectly with Asp-74 (located in domain I). These water-mediated interactions are, in addition to the interactions mediated by the trimethylammonium head group of choline, the only interactions observable between domains I and II of the OpuBC protein (Fig 3B).

Mutational analysis of the choline-binding site in OpuBC

The architectures of the aromatic cage that coordinates the bulky cationic head groups of choline in OpuBC (Fig 3B) and glycine betaine in AfProX (38) via cation- π interactions are super-imposable (Fig 4). The spatial orientation of the side chains of Tyr-71, Tyr-117, Tyr-197 and Tyr-221 from OpuBC overlay perfectly with the four Tyr residues (Tyr-63, Tyr-111, Tyr-190 and Tyr-214) present in the AfProX glycine betaine-binding site. As a consequence of this architectural arrangement, the trimethylammonium head groups of choline and glycine betaine are coordinated identically in both crystal structures. The ProX protein from the hyperthermophile *A. fulgidus* binds its ligand glycine betaine with a K_d of about 50-60 nM (Tschapek *et. al.* submitted). The replacement of single Tyr-residues within the aromatic cage of AfProX by Ala-residues causes a drop in ligand binding, depending on which Tyr-residues is mutated. Hence, a mutant aromatic cage formed by only three Tyr-residues still affords ligand binding by the AfProX solute receptor with a reasonable affinity. However, the simultaneous replacement of two Tyr-residues by Ala-residues (regardless in which combination) generates AfProX mutant proteins that are no longer proficient in glycine betaine binding (Tschapek *et. al.* submitted).

Since the aromatic cages present in the ligand binding sites of ProX and OpuBC have an identical architecture (Fig 4), we have not repeated a mutational analysis of the aromatic cage of the OpuBC protein. We surmise that the data obtained on ligand binding for the AfProX protein can be projected onto the ligand-binding attributes of the OpuBC protein. Instead, we conducted a mutational analysis of the residue coordinating the alcohol function of choline and those residues that contributes to domain-domain interactions of the two lobes of the OpuBC protein and the build-up the water network that stabilizes the ligand within the binding site.

Therefore, we focused on Gln-19, Asp-74, Asp-149 and Leu-155; each of these residues was replaced by an Ala-residue and each of the purified mutant OpuBC proteins was analyzed by intrinsic Trp/Tyr fluorescence. Replacement of Gln-19 by Ala reduced the binding affinity by about 14-fold (Table 2), highlighting the importance of the direct interaction of the Gln-19 side-chain with the alcohol group of choline (Fig 3B) for high affinity ligand binding. However, those residues that are involved in setting the water network within the ligand-binding site were (at least) of equal importance to the contribution of Gln-19 to ligand binding. The separate replacement of Asp-149 and Leu-155 with Ala residues led to a 18-fold and 25-fold drop in ligand binding activity, respectively (Table 2). The simultaneous substitution of these two residues with Ala residues led to an OpuBC variant with a K_d of about 1132 μM , a 38-fold drop in ligand affinity exhibited by the wild type OpuBC protein (K_d of about 30 μM (Table 2)). A key residue within the ligand-binding site is Asp-74. The side-chain of Asp-74 does not make any direct contacts to the choline ligand, but it catalyzes via water-mediated interactions between Gln-19, Leu-155 and Asp-149 the closure of the two domains of the OpuBC protein. It is thereby critical for the stable entrapment of the choline ligand (Fig 3B). Replacement of Asp-74 by an Ala-residue generates an OpuBC mutant protein that is unable to bind choline, even when the ligand is present at a concentration of 50 mM in the binding assay (Table 2). Likewise, the simultaneous replacement of the residue that makes a direct contact to the choline ligand (Gln-19) and Leu-155, a key residue for the formation of the water network (Fig 3B), with Ala residues leads to an OpuBC protein that no longer can bind choline (Table 2). Collectively, this mutational assessment of the ligand-binding site of the OpuBC solute receptor underscores the functional roles of those residues that were deduced from the crystal structure of OpuBC for both direct (Gln-19) and water-mediated interactions (Asp-74, Asp-149, Leu-155) with the choline ligand and the two lobes of the OpuBC protein.

It is generally thought that the interaction of the ligand with residues in the substrate-binding site induces a hinge-bending (and sometimes also a rotational motion) movement of the two domains of the binding protein. As a result, the substrate-binding site is dynamically formed with contributions of residues from both domains of the binding protein that then lead to the entrapment of the ligand and the formation of the closed conformation of the binding protein. The hinge segments that connect the two lobes play a critical role for these domain movements (41, 44, 46). Asn-115 is part of one of the hinge segments present in OpuBC and its replacement by Ala destroys the ability of OpuBC to bind its ligand (Table 2).

Comparison of the choline-binding site of OpuBC with the glycine betaine-binding site present in ProX from *A. fulgidus*

The architectures of the aromatic cage for the coordination of the trimethylammonium headgroups of choline in OpuBC (Fig 3B) and glycine betaine in AfProX(38) via cation- π interactions are super-imposable (Fig 4). Despite the identical spatial

orientation of the side chains of the four Tyr residues forming the aromatic cages, it should be recalled that the *B. subtilis* OpuBC protein does not bind glycine betaine (data not shown). Conversely, the ProX protein from *A. fulgidus* does not bind choline (Tschapek *et. al.* submitted). We traced these differences in ligand-specificity to the way in which the AfProX and OpuBC proteins coordinate the carboxylate group of glycine betaine and the alcohol group of choline, respectively.

An important role for the fixation of the choline ligand within the substrate-binding site of OpuBC plays the side chain of Gln-19, since it interacts directly with the alcohol group of the choline molecule (Fig 3B). At the equivalent position in the glycine betaine-binding site of AfProX, a lysine residue (Lys-13) is present that interacts with one oxygen of the carboxy tail of glycine betaine (Fig 4). The other hydroxyl group of glycine betaine is coordinated through interactions with Arg-149 (38). As described above, the interaction between both domains of OpuBC is mediated via a water network into which Leu-155 is critically involved (Fig 3B) (Table 2). Strikingly, in the overlay of the OpuBC and AfProX crystal structures, a water molecule is located exactly at the position of the N3 atom of the glycine betaine-contacting Arg-149 residue of AfProX (Fig 4). Hence, the strong interaction partners for the carboxylic tail of glycine betaine present in the ProX protein from *A. fulgidus* are absent in the OpuBC protein from *B. subtilis* (Fig 4). As a result, glycine betaine cannot be bound effectively despite the fact that its trimethylammonium head group would in all likelihood fit without any problems correctly into the aromatic Tyr-cage of the OpuBC protein.

Our analysis of the crystal structures of the OpuBC and AfProX proteins therefore suggests that glycine betaine can only fleetingly interact with the open conformation of the OpuBC protein and is unable to induce a closure of the two domains of OpuBC to entrap it stably and thereby form the closed conformation of the solute receptor. This conformation, however, is required for the productive interactions of the substrate-loaded binding proteins with the membrane-embedded components of the cognate ABC transport system (35, 47) to release the ligand into the translocation pathway for ATP-hydrolysis-dependent import of the substrate into the microbial cell (31, 32). Hence, the crystal structure of the OpuBC protein in complex with its natural ligand choline provides a rationale for the observed choline-specificity of the OpuB ABC transporter and its inability to catalyze the import of glycine betaine into the *B. subtilis* cell (23).

Analysis of the crystal structure of OpuCC from *Staphylococcus aureus*, a ligand binding protein related to the OpuBC and OpuCC proteins from *B. subtilis*

In the Brookhaven Protein Databank (www.pdb.org), a crystal structure (1.9 Å) of a substrate binding protein (OpuCC) from a *Staphylococcus aureus* strain has been deposited (PDB code 3O66). This structure has been determined by a structural genomics consortium but has not been published yet; the OpuCC protein is annotated in the PDB as a glycine betaine/carnitine/choline binding protein but no functional data are available for this protein

to assess its true substrate specificity. However, a sequence-related OpuCC protein from the *S. aureus* strain RN6390 is part of a functionally characterized ABC-importer for choline.(48) Due to the high degree of amino acid sequence identity (>60 % identity and >80 % homology) towards the *B. subtilis* OpuBC protein (Fig 5), we compared the crystal structures of the OpuCC_{s.a}-3O66 and OpuBC proteins. The superimposition of both structures (Fig 6) revealed that the OpuCC_{s.a}-3O66 structure has been crystallized in the open unliganded conformation. This open conformation is stabilized by two triethylene glycol molecules bound between both domains of the OpuCC_{s.a}-3O66 protein, a position where the physiological relevant ligand is expected to be localized (41, 46). Presumably, the two triethylene glycol molecules present in the OpuCC_{s.a}-3O66 structure have likely been captured from the crystallization condition.

Conclusion

The crystal structure of choline bound OpuBC from *B. subtilis* expand our knowledge on substrate binding and the determinants for differences in affinity of SBPs involved in osmoprotection. The excessive mutation of amino acids involved in ligand binding of AfProX and OpuBC and subsequent affinity measurements resulted in the conclusion that the aromatic box which interacts via cation- π -interactions with the substrate's trimethyl ammonium head group has a rather low influence on affinity to the substrate. However, most important are amino acids involved in domain-domain interactions, that stabilize the closed conformation of the SBP. At this point the nature of interaction seem to determine somehow the quantitative value of affinity. In our case AfProX shows direct interactions via hydrogen bonds of residues of domain I and II and therefore wild type protein has a K_D of 50-50nM. This is rather high when compared to OpuBC: Here only water mediated interactions between domain I and II can be identified and measured K_D for wild type is more than 600 fold lower than affinity constant of ProX. Thus microorganisms the binding site in SBP binding osmolytes needs to be mutated at one or two amino acids positions to adjust affinity to match their requirements.

Materials and Methods

Chemicals

Choline, glycine betaine, anhydrotetracycline and desthiobiotin were purchased from Sigma-Aldrich (Munich, Germany). The antibiotic ampicillin was purchased from Carl Roth (Karlsruhe, Germany) and gentamycin was obtained from Serva (Heidelberg, Germany). The matrix (*Strep-Tactin* Sepharose) for affinity purification of *Strep*-tag-II marked recombinant proteins were purchased from IBA (Göttingen, Germany).

Bacterial strains and growth media

Chromosomal DNA of the *B. subtilis* wild type strain JH642 (*trpC pheA1*; BGSC 1A96; a kind gift of J. Hoch, Scripps Research Institute, CA, USA) was used as the donor for the cloning of the *opuBC* gene. Strain JH642 was propagated aerobically in Luria-Bertani liquid medium at 37° C (49). The *Escherichia coli* strain DH5 α (Fermentas, St. Leon-Rot, Germany) was used for all cloning experiments. For the overproduction of the recombinant *B. subtilis* OpuBC protein and its mutant derivatives, we used the *E. coli* strain BL21 [Artic express (DE) RIL] (Stratagene; La Jolla, CA, USA). Overproduction of OpuBC and its derivatives was carried out in a slightly chemically defined minimal medium (MMA)(49) supplemented with 1mg/L thiamin, 1mM MgSO₄, 0.2% casamino acids (w/v) and 0.5% glucose (w/v) as the carbon source and 100 μ g/ml ampicillin to select for recombinant plasmids carrying the *opuBC* gene or its mutant derivatives.

Cloning and site-directed mutagenesis of the *B. subtilis opuBC* gene

The OpuBC choline binding protein from *B. subtilis* is initially synthesized with a cleavable 22-residue N-terminal signal sequence for export via the Sec-pathway from the *B. subtilis* cell; the signal sequence is proteolytically processed and the newly formed N-terminus of the mature protein (Cys-23) is lipid-modified (23). The coding region of *opuBC* was cloned without the DNA segment that encodes the signal sequence and the codon for Cys-23 was replaced by a codon encoding a Gly residue. A PCR-reaction was carried out with the forward (5'-CGTCTCCGCGCGGCTCGCTTCCTGGTCTCAGCGC-3') and backward (5'-CGTCTCGTATCTCACGATTCGAAATAGCGATGTTTTTC-3') primers on chromosomal DNA isolated from the *B. subtilis* wild type strain JH642. The resulting 877 bp *opuBC* DNA fragment was then cleaved with the restriction enzyme *Esp3I* (recognition sequences in the primer sequence are underlined) and then cloned into the expression vector pASK-IBA6 (IBA, Göttingen, Germany) which had been cut with *Bsal*. The DNA sequence of one of the resulting plasmids, pMP31, was determined (eurofins MWG operon; Ebersberg, Germany) to ensure that no undesired mutations had been introduced into the *opuBC* coding sequence during the cloning procedure. In plasmid pMP31, the coding region of *opuBC* is inserted into the pASK-IBA6 vector in such a way that it is fused to an OmpA signal sequence followed by

the *Strep*-tag-II affinity peptide and a cleavage site for the Factor Xa protease. Expression of the hybrid *opuBC* gene in plasmid pMP31 is under the control of the anhydrotetracyclin (AHT)-responsive TetR repressor that is encoded by the pASK-IBA6 expression vector.

Mutant derivatives of the *opuBC* gene were generated with the QuickChange site-directed mutagenesis kit (Statagene, La Jolla, CA) using plasmid pMP31 as the DNA template and custom-synthesized mutagenic DNA primers (purchased from Sigma-Aldrich, Munich, Germany). The following mutant *opuBC* plasmids were created: pMP49 [Gln-19 →Ala (CAA/GCA)], pMP51 [Asp-74 →Ala (GAC/GCC)], pMP52 [Asn-115 →Ala (AAT/GCT)], pMP53 [Leu-155 →Ala (CTC/GCC)] and pMP65 [Asp-149 →Ala (GAT/GCT)]. Selected mutant plasmids with single amino acid substitutions in the OpuBC protein were re-mutagenized to generate the following double *opuBC* derivatives: pMP62 [Gln-19 →Ala (CAA/GCA) and Leu-155 →Ala (CTC/GCC)] and pMP66 [Asp-149 →Ala (GAT/GCT) and Leu-155 →Ala (CTC/GCC)]. The entire coding region of each of the mutant *opuBC* alleles was sequenced to ensure the presence of the desired mutation and the absence of unwanted DNA alterations.

Overexpression and purification of recombinant OpuBC proteins in *E. coli*

Plasmid pMP31 (resistant to ampicillin) was transformed into competent cells of the *E. coli* strain BL21 [Artic express (DE) RIL] (resistant to gentamycin) by simultaneously selecting for ampicillin (100 µg/ml) and gentamycin (20 µg/ml) resistant transformants on LB agar plates. One antibiotic resistant colonies was then picked and used to inoculate a pre-culture (100 ml modified MMA containing the antibiotics ampicillin and gentamycin at the above indicated concentrations) that was then propagated over-night at 37°C in a 1 L Erlenmeyer flask in an aerial shaker set at 200 rpm. For the main culture, we used a Minifors fermenter system (Infors AG, Bottmingen, Switzerland) with a 5 L reaction vessel filled with 4 L modified MMA (see above) containing 100 µg/ml ampicillin. The medium present in the fermenter vessel was inoculated with the pre-culture of strain BL21 [Artic express (DE) RIL] to an OD₅₇₈ of about 0.1. The cells were then grown at 37°C first as batch culture (up to an OD₅₇₈ of about 3) and subsequently grown as a fed-batch culture up to an OD₅₇₈ of about 15. Subsequently, the temperature of the culture was cooled-down to 20°C and the expression of the TetR-controlled *opuBC* gene present on plasmid pMP31 was induced by the addition of anhydrotetracyclin (0.2 µg anhydrotetracylin/ml culture) to the culture. The bacterial cells were then propagated under *opuBC*-inducing conditions for additional 16 h at 20°C and were subsequently harvested by centrifugation (30 min, 3 000 x g at 4°C). The cells (10 g wet weight) were re-suspended in 20 ml buffer W [100 mM Tris-HCl (pH 7.5), 150 mM NaCl] and then were disrupted by passing them five-times through a French-pressure cell (1000 psi) at 4°C. Unbroken cells and cellular debris were removed by ultracentrifugation (1 h, 35 000 x g at 4°C) and the supernatant was then loaded onto a 10-ml *Strep*-Tactin column (IBA, Göttingen, Germany) pre-equilibrated with 10 bed volumes of buffer W [100 mM Tris-HCl (pH

7.5) 150 mM NaCl]. After washing the column with 20 bed volumes of buffer W, proteins bound to the affinity matrix were eluted with three bed volumes of buffer E [100 mM Tris-HCl (pH 7.5), 150 mM NaCl, 2.5 mM desthiobiotin]. Two forms of the recombinantly produced OpuBC protein were found: (i) the non-processed OmpA-*Strep*-Tag-II-OpuBC protein and (II) the processed *Strep*-Tag-II-OpuBC protein.

All fractions containing OpuBC proteins were pooled and concentrated using Vivaspin 4 concentrator columns (exclusion size, 10 kDa) (Vivascience, Hannover, Germany) with a simultaneous exchange of the buffer to 10 mM Tris-HCl (pH7.5) and 10 mM NaCl. The non-processed OmpA-*Strep*-Tag-II and the processed *Strep*-Tag-II portions of the OpuBC protein were then treated with the factor Xa protease (Merck, Darmstadt, Germany) to remove the OmpA signal sequence and the *Strep*-Tag-II affinity peptide. Proteolytic cleavage of the recombinant OpuBC protein with Factor Xa was carried out at room temperature over-night [0.5 U per 50 µg of OpuBC protein in the cleavage buffer provided by Merck (Darmstadt, Germany)]. The completeness of the proteolytic cleavage of the two forms of the recombinant OpuBC protein was assessed by SDS-gel electrophoresis and found to typically yield a single OpuBC band on a 12% SDS-polyacrylamide gel (see Fig. 2A). The OpuBC protein was then applied to a 5 ml ion exchange column (HiTrap Q FF 5ml; GE Healthcare, Munich, Germany) equilibrated with two bed volumes of buffer A [25 mM Tris-HCl (pH 7.5), 20 mM NaCl]. We observed that a approximately 50% of the OpuBC protein passed right through the ion exchange column and this portion of the purified OpuBC protein was subsequently found to be inactive in ligand binding experiments using fluorescence spectroscopy (see below). Functional OpuBC protein (as assayed by subsequent fluorescence spectroscopy) was eluted from the HiTrap Q FF 5ml column by applying a gradient of buffer B [25 mM Tris-HCl (pH 7.5), 1 M NaCl]. From a typical overproduction (from 4 l of culture) and purification experiment, we obtained approximately 20 mg of pure and biologically active OpuBC protein. For crystallization trials and ligand binding experiments, the purified OpuBC protein was concentrated to about 10 mg/ml with Vivaspin 4 concentrator columns (exclusion size, 10 kDa) (Vivascience, Hannover, Germany) with a simultaneous exchange of the buffer to 10 mM Tris-HCl (pH7.5) and 10 mM NaCl. All mutant derivatives of OpuBC were overproduced and purified as described above for the wild type protein.

Determination of the dissociation constant of the OpuBC-choline complex

The dissociation affinity of the OpuBC-choline complex was determined by intrinsic tyrosine and tryptophan fluorescence spectroscopy as described for the glycine betaine binding protein OpuAC from *B. subtilis* (36, 37). The OpuBC protein possesses three Trp and 17 Tyr residues and the intrinsic fluorescence of these residues was monitored from 295 nm to 400 nm using a Cary Eclipse fluorescence spectrometer (Varian, Surrey, United Kingdom). The excitation wavelength was set to 285 nm, the slit width was 5 nm, and the temperatures during the assays was maintained at 25°C with a cooling/heating device. One ml sample of 1

μM OpuBC protein (in 10 mM Tris-HCl; pH 7.5) was equilibrated for 15 min in the measuring cuvette. Subsequently, different amounts of choline (1 μM to 200 μM) were titrated to the OpuBC protein solution and the fluorescence was recorded. Upon choline binding, an increase in the fluorescence intensity of OpuBC was detected (Fig. 2B), and this change in the emission spectrum was used to determine the apparent K_d value for the OpuBC protein for choline binding by plotting the change in fluorescence intensity at 339 nm against the choline concentration used in the assays. The recorded data were analyzed by assuming a standard one-site-binding model. All given K_d values of the wild type OpuBC protein and its mutant derivatives (Table 2) represent the average of three independent measurements, with the standard deviations given as errors.

Crystallization of the OpuBC-choline complex, data collection and model refinement

Crystals of OpuBC were obtained using the hanging-drop vapor diffusion technique at 12°C. Purified OpuBC was concentrated to 10mg/ml and incubated with 15 μM choline chloride prior to crystallization. 1 μl of protein was mixed with 1 μl of reservoir solution containing 200 mM potassium acetate and 20% PEG3350. Crystals appeared after 3 days and were harvested after 2 weeks in 200 mM potassium acetate, 20% PEG3350 and 30% ethylenglycol and flash frozen in liquid nitrogen.

A native dataset of the OpuBC-choline complex was collected at beamline ID23-eh1 (ESRF, Grenoble, France) and scaled using XDS (39). Initial phases were obtained by molecular replacement using the program PHASER (40) with the crystal structure of *Archaeoglobus fulgidus* glycine betaine binding protein ProX as a template (PDB entry 1SW2)(38). Data refinement statistics and model content are summarized in Table 1. Model building and refinement were performed using coot and REFMAC5 (50).

Sequence alignments and Structure alignments

Amino acid sequence alignments of proteins related to the *B. subtilis* OpuBC protein were performed with ClustalW (51).

Structure alignments were performed using LSQMAN employing standard settings.

Figure preparation

Figures of protein structures were prepared using PYMOL (<http://pymol.sourceforge.net/>).

Protein Data bank accession number

The coordinates of the OpuBC-choline complex will be deposited in the RCSB Protein Data Bank.

Figure Legend

Figure 1:

The osmoprotectant uptake systems of *B. subtilis* and the synthesis pathway of glycine betaine from the precursor choline. The OpuA, OpuB and OpuC osmoprotectant uptake (Opu) systems are members of the ABC family (21, 23), the OpuD osmoprotectant uptake system is a member of the BCCT family (22, 52). The OpuA, OpuB and OpuC transporters possess extracellular solute receptors (OpuAC, OpuBC, OpuCC) that are each tethered to the outer face of the cytoplasmic membrane through a lipid modification of an N-terminal Cys-residue (23, 53). The OpuA transporter possesses a single integral membrane component (OpuAB) that likely functions as a homodimer; the integral membrane components of the OpuB transporter (OpuBB, OpuBD) and that of the OpuC transporter (OpuCB, OpuCD) are likely to function as a heterodimer. Each of the OpuA, OpuB and OpuC ABC transporters possesses a single ATPase (OpuAA, OpuBA, OpuCA) protein that probably function as dimers (31, 32). The substrate specificities of the various Opu transporters have been assessed through osmoprotection growth assays and transport studies with high salinity challenged *B. subtilis* cells (21-23, 28-30). The synthesis pathway of glycine betaine from the precursor choline has been elucidated by Boch *et al.* (15, 19). Glycine betaine production in *B. subtilis* is catalyzed by the sequential enzymatic reactions of an alcohol dehydrogenase (GbsB) and a glycine betaine aldehyde dehydrogenase (GbsA).

Abstract

The substrate binding protein (SBP) ProX from *A. fulgidus* is highly selective for glycine betaine (GB) and proline betaine, which are required for thermoprotection to counterbalance temperature fluctuation in the habitat. A detailed mutational analysis of the substrate-binding site revealed the contribution of individual amino acids for ligand binding. Interestingly, exchange of a single amino acid, Arg149, displayed the largest impact. To gain further insights, the structure of a mutant was solved in the liganded-open conformation. Here, GB is bound differently compared to the liganded-closed structure. A network of amino acid side chains communicates the presence of GB towards Arg149, which increases ligand affinity and induces domain closure. These results are corroborated by molecular dynamics studies and support the view that a single amino acid acts as a switch to induce the high affinity state of the SBP.

Introduction

Many microorganisms import a variety of chemical compounds from environmental sources through high-affinity transport systems, many of which belong to the family of ATP Binding Cassette (ABC) transporters (7). These systems depend strictly on a so-called substrate binding protein (SBP) that captures the ligand with high affinity and subsequently delivers it to its cognate transporter (4). The SBP thereby determines the directionality of the overall transport reaction, and its interaction with the transmembrane domain of the transporter regulates the ATPase activity of the nucleotide-binding domain of the transport complex (4, 47).

Structural studies of a substantial number of SBPs revealed a common fold with a bilobal organization connected via a linker region (48, 49). In the ligand-free, open conformation, the two lobes or domains are separated from each other, thereby forming a deep, solvent exposed cleft, which harbors the substrate-binding site. Upon ligand binding, both domains of the SBP move towards each other through a hinge-bending motion or rotation, which results in the so-called liganded-closed conformation. As a consequence of this movement, residues originating from both domains generate the ligand-binding site and trap the ligand deeply within the SBP (48). In the absence of a ligand, unliganded-open and unliganded-closed states of the SBP are in equilibrium, and the ligand solely shifts this equilibrium towards the liganded-closed state. This sequence of events has been coined the “Venus-fly trap mechanism” (29, 50, 51), which is supported by numerous crystal structures in the absence and presence of a ligand (52, 53) and other biophysical techniques (48).

For the maltose binding protein (MBP) from *Escherichia coli* (4), the paradigmatic SBP, it has been shown that both domains are dynamically fluctuating around an average orientation in the absence of the ligand (54). NMR spectroscopy of MBP in solution revealed that the ligand-free form of MBP consists of a predominantly open species (95%) and a minor species (5%) that corresponds to a partially closed state; both forms co-exist in rapid equilibrium (55). The open form of MBP observed by NMR is similar to the crystal structure of the unliganded-open conformation (56). However, the partially closed species detected by NMR (55) does not correspond to the ligand-bound, fully closed form found in crystallographic studies. Instead, it represents an intermediate, partially closed conformation (57), suggesting that the substrate is required to reach the final, liganded-closed conformation.

In line with this suggestion, Millet *et al.* have shown that every degree of domain closure in the unliganded MBP requires a conformational deformation energy of approximately 212 cal/mol. Since MBP closes by about 20°, this would lead to an energetic cost of ~ 4 kcal/mol when forming the unliganded-closed conformation of MBP (58). This unliganded-closed state, first observed by X-ray crystallography, is therefore highly unfavorable, and resembles a loaded spring (58). Changing the stiffness of this region by introducing amino acids with bulky

side chains changes the degree of closure of MBP, which directly correlates with maltose binding affinity (58).(59). As a consequence, mutations in the hinge region likely alter the equilibrium between the open and partially closed states of MBP (55). Upon maltose binding, a further shift in this equilibrium occurs towards the fully liganded-closed conformation, which becomes accessible because maltose forms favorable interactions with the protein.

Generally, the hinge region provides MBP with a large degree of flexibility. This allows MBP to bind a variety of malto-oligosaccharides, some of which lead to domain closure (56, 60). Although this highlights a distinct role of the substrate in domain closure, the exact nature of the substrate-induced closing mechanism of MBP and SBPs in general is unknown. Furthermore, SBPs bind their substrates with high affinity (in the low μM or even nM range) (48) but it is not fully understood how the substrate is released to its cognate ABC importer. One scenario could be that interactions between the ABC transporter and the SBP during the transport cycle lead to a modulation of the SBP's affinity to its substrate(47).

In the sulfate-reducing thermophilic Archaeon *Archaeoglobus fulgidus* (*Af*), the ABC importer ProU has been annotated as a specific uptake system for the compatible solutes glycine betaine (GB) and proline betaine (PB) (61). The corresponding SBP (*AfProX*) has been crystallized in different conformations: a liganded-closed conformation in complex either with GB or PB as well as in an unliganded-open conformation (62). Here, we present the structure of *AfProX* in the liganded-open conformation together with a systematic mutational analysis of the binding site of *AfProX* and molecular dynamics simulations of liganded *AfProX*, using starting structures of different conformational states. Based on our results, residue Arg149 is crucial for the switch from a low-affine open structure of *AfProX* to a high-affine closed state. Furthermore, we elucidate the role of the substrate in this process, whose presence is communicated through a network of amino acids located in both domains of *AfProX*, ultimately triggering domain closure. Our data implies that the "Venus-fly trap" mechanism is overlaid with distinct molecular events to ensure the specific biological function of SBPs.

Results

Thermoprotection of the hyperthermophilic archaeon *A. fulgidus* by GB and PB

AfProX possesses striking substrate specificity: from all of the osmoprotectants tested only GB and PB are substrates (Figure 1A). Both, GB and PB, typically function as protectants in microorganisms especially during changes in the salinity, which lead to osmostress. However, we observed that these compounds had no osmoprotective effect for *A. fulgidus* (Supplementary Figure 1). Therefore, the uptake of GB or PB must serve another physiological role. Since GB has been shown previously to serve as a thermoprotectant in different bacteria⁽⁶³⁾, we explored a possible thermoprotective effect of GB and PB for *A. fulgidus*. Neither GB nor PB had any effect on the growth of this archaeon when it was cultivated at its optimal growth temperature of 83°C (Supplementary Figure 1). In contrast, both compounds exerted a striking thermoprotective effect on cell growth at an elevated growth temperature of 90°C. Without GB or PB, *A. fulgidus* was unable to grow at that temperature (Figure 1B). To our knowledge, such thermoprotection has only been observed for organisms living at moderate temperatures but never for a hyperthermophile.

Mutational analysis of the ligand-binding site in AfProX

AfProX has been crystallized with GB or PB at a resolution of 2.1 Å and 1.9 Å, respectively (62). The positively charged trimethylammonium head group of GB and the dimethylammonium head group of PB are wedged into an aromatic cage that is formed by the main chain carbonyl of Asp109 at the bottom and by four Tyr residues (Tyr63, Tyr111, Tyr119, Tyr214) forming the four faces of a box. Here, cation- π interactions are key determinants for coordinating the head group. The carboxylic tails of GB and PB protrude from this partially negatively charged cage and form two salt bridges and one hydrogen bond with Lys13, Thr66, and Arg149, respectively (62). We have measured the binding of GB and PB to AfProX using fluorescence spectroscopy and determined a K_D of 60 ± 10 nM and 50 ± 10 nM, respectively (Supplementary Table 1). To further support this high but not unusual affinity of SBPs (49, 64), we also determined the binding constant of GB by isothermal calorimetry (ITC) and revealing a K_D of 100 ± 30 nM (Supplementary Figure 2). This value is within experimental error identical to the K_D determined by fluorescence spectroscopy.

To assess the contribution of individual residues within the substrate-binding site, we carried out a systematic mutagenesis study. The individual replacement of the four Tyr residues forming the aromatic cage reduced the binding affinity between 60-fold and 2400-fold for GB and between 60-fold and 4500-fold for PB (Supplementary Table 1). The simultaneous

replacement of two Tyr residues by Ala, regardless of the combination, abolished ligand binding, highlighting the importance of the aromatic cage. The individual substitution of Lys13, Thr66, and Arg149 by Ala also resulted in a decreased ligand binding affinity. The largest decrease, however, was observed for the Arg149Ala mutation, which exhibited a K_D of $320 \pm 60 \mu\text{M}$ for GB (Supplementary Table 1), a 5000-fold reduction in binding affinity, while no binding of PB could be detected. Therefore, Arg149 is of high importance in AfProX.

Crystal structure of Tyr111Ala AfProX

The Tyr mutations of the aromatic box had an unexpectedly large effect on the affinity of GB. Therefore, we crystallized one of these mutants, Tyr111Ala, and solved its structure in the presence of GB at 2.0 Å. Tyr111Ala has an affinity of $76 \pm 4 \mu\text{M}$ towards GB (Supplementary Table 1). Crystallization conditions are given in Materials and Methods and data statistics are shown in Supplementary Table 2. The structure of Tyr111Ala AfProX consists of two domains, the ligand GB, and a HEPES molecule captured from the crystallization solution. A comparison with the unliganded-open and a liganded-closed structure revealed that the structure of Tyr111Ala AfProX adopts a liganded-open conformation, with the hinge region positioned between residues 109-111 and 213-215 (Figure 2). A comparison between the liganded-open and unliganded-open structure revealed that only one loop (amino acid 142 to 153) differs. This loop contains Arg149 that is part of the substrate-binding site in the liganded-closed structure and will be referred to as “Arg-loop” henceforth.

The substrate-binding site of the AfProX Tyr111Ala variant

In the AfProX Tyr111Ala mutant, the trimethylammonium moiety of GB is located at the same position as in the liganded-closed structure (Figure 3). Although GB lacks interactions with Tyr111, it is bound by Tyr63, Tyr190, and Tyr214 of the aromatic cage and further stabilized by interactions with Thr66, Asp109, and the piperazinyl ring of the bound HEPES. Notably, when compared to the closed structure of the wild type protein, the carboxyl tail of GB is rotated by almost 180° in the AfProX Tyr111Ala mutant. Here, GB interacts through a water molecule with Thr66 and through two water molecules with the side chain of Tyr190. As the carboxyl group of GB neither forms a direct nor a water-mediated interaction with the HEPES molecule, the orientation of GB should not be influenced.

The architectures of the binding sites in the liganded-closed, liganded-open, and unliganded-open structures of AfProX are closely related because Tyr63, Tyr214, Lys13, Thr66, and Asp109 are superimposable in all three structures (Figures 4A and 4B). However, the side chain of Tyr190 is flipped in the closed structure by 130° when compared to both open structures. Interestingly, the position of the Tyr111 side chain in the liganded-closed structure is

located at the position of the side chain of Tyr190 in the unliganded-open and liganded-open structure (Figures 4A and 4B). These observations imply that during the opening and closing movements of AfProX, the binding site does not undergo a major conformational change; rather, it is largely pre-formed in the unliganded-open structure and, thus, pre-dispositioned to capture GB. Still, the side chains of Tyr111 and Tyr190 need to reorient. Furthermore, the largest movement is observed for the Arg-loop, which moves by approximately 10Å, starting from an outward-rotated orientation. This leads to side chain interactions of Arg149 with GB, Tyr111, and Thr66, thereby complementing and locking the binding site.

The role of Arg149

In addition to the direct interaction of Arg149 with GB and residues that are part of the substrate-binding pocket (Tyr111, Thr66), Arg149 is a major determinant in domain-domain interactions in the closed structure (Supplementary Table 3). As such, Arg149 interacts with Val70 (domain I) and Asp151 (domain II), thereby acting as a linking element between the two domains enforcing a stable domain closure. These interactions complement those mediated by Pro172 of domain II, where Pro172 interacts via its C α -atom and a water molecule with Glu155 of domain II. Together, this provides a further explanation for the crucial role of Arg149 for the stability of the liganded-closed state. This crucial role is manifested by a drop in affinity towards GB and abolished binding of PB (Supplementary Table 1) when replacing Arg149 by Ala.

Partial domain closure of AfProX occurs even in the absence of GB

To study the role of Arg149 with respect to the domain closure of AfProX in further detail, we performed molecular dynamics (MD) simulations starting from the liganded-open AfProX structure with bound GB. Here, Ala111 was mutated *in silico* to Tyr in the Tyr111Ala AfProX crystal structure. After 50 ps of MD simulation, GB reoriented from the configuration observed in the AfProX Tyr111Ala crystal structure to the configuration seen in the closed structure (Supplementary Figure 4). In the initial configuration, only water-mediated interactions are formed between the carboxyl moiety of GB and AfProX. After the reorientation, the carboxyl moiety of GB forms a hydrogen bond with Thr66 and a salt bridge with Lys13. Furthermore, after 4 ns of MD simulation, GB dissociates from AfProX and does not re-associate during another 196 ns of simulation time (Supplementary Figure 5). Notably, after 50 ns of MD simulation, unliganded AfProX undergoes a drastic conformational change: domain II comes as close as 2 Å rmsd to the configuration found in the closed AfProX structure (Supplemental Figure 5). During the remaining 150 ns of MD simulation, domain II repeatedly opens again but always returns to the configuration akin to the closed structure. In summary, MD simulations

started from the open AfProX structure reveal that a tendency to domain closure exists even in the absence of GB. Such motions are inline with the “Venus-fly trap mechanism” (48) and have been experimentally verified for MBP (55).

Coupled structural reorganization in the binding site upon domain closure

In order to determine in atomic detail the coupling of conformational changes in the ligand-binding site that occurs upon domain closure in the presence of GB, MD simulations starting from the liganded-open AfProX structure were repeated. However, this time GB was restrained to the ligand-binding site to prevent dissociation. Again, a domain closure was observed, with domain II coming as close to the ligand-bound bound state as 4.2 Å rmsd (Figures 5A and 6A). Notably, this state is reached after 11 ns, about five times faster than in the absence of GB (Figure 5A). Although single events that occur only once during a MD simulation must be interpreted with caution, these results indicate that binding of GB facilitates conformational changes occurring during the transition from the open to the closed state. Furthermore, domain closure is accompanied by a reorientation of GB (Figure 5A). In parallel, the Tyr cage that coordinates the binding of the trimethyl ammonium moiety of GB via cation- π interactions starts to adopt the conformation observed in the closed structure (Figure 5B). In this process, Tyr111 shifts about halfway between the conformations of the open and the closed structures, whereas the conformation of Tyr190 is still close to the one observed in the open structure (Figure 6B). For Tyr111 to reach its final position, Tyr190 must reorient. In addition, the minimal distance between any Oe atom of Glu145 and any NH atom of Arg149 fluctuates between 2.8Å and ~ 6 Å during the first 8 ns of simulation time (Figure 5B), indicating the temporary formation of a salt bridge. This salt bridge consolidates during the next 2 ns, after which it is almost permanently formed for another 2 ns. Subsequently, upon domain opening after about 12 ns of simulation time, the interaction between Glu145 and Arg149 breaks up, and Glu145 and Arg149 remain fluctuating between a salt bridge-formed state and complete separation for the remainder of the simulation time. Thereby, maxima of the domain II-rmsd curve (Figure 5A) are significantly paralleled by large Glu145-Arg149 distances (Figure 5B), again demonstrating in a remarkable way the coupling of events that lead to domain closure and opening of the AfProX protein.

In order to further investigate the central role of Arg149 for the domain closure of AfProX, unrestrained MD simulations started from liganded-closed wild type and Arg149Ala AfProX structures were performed. Over the course of 50 ns of simulation time, the wild type structure starts to open up once but immediately returns to the closed conformation (Figure 7). In contrast, opening of the domains is observed earlier, more frequently, and more pronounced in the Arg149Ala structure. Most notably, after opening, the Arg149Ala structure never regains the closed conformation again.

Substrate binding triggers domain closure to a closed state with a “loaded spring”

The above-described experiments unambiguously established the importance of Arg149 for the high-affine binding of GB (or PB) to AfProX. Furthermore, AfProX is essential during thermal fluctuations in the habitat of *A. fulgidus* (see above), and the response to such fluctuations must be fast. Thus, binding and release of GB (or PB) to and from AfProX must be fast, too. This raises the question if an initial binding of GB (or PB) can trigger a domain closure leading to a closed conformation stabilized by Arg149. To identify such a possible triggering mechanism, we analyzed interactions of the bound substrate in the liganded-open structure with Arg149. Already in this state, the presence of GB is communicated to Arg149 through interactions of the side chains of Tyr190, Tyr111, and Phe146; that is, GB and Arg149 are connected with each other via a direct side-chain network. Interestingly, this network does not change from the open to the closed structure as judged by unaltered distances between these amino acids in both states.

Together with the information from MD simulations, this suggests the following substrate-induced triggering mechanism in AfProX. As highlighted in Figure 8A, the open conformation appears to be stable and ready to bind GB (or PB) due to the largely preformed ligand-binding site. The next state, after GB binding, is represented by the liganded-open structure of AfProX presented here (Figure 8B). In this state, GB interacts with Tyr190 (distance between the C_α atom of GB and the C_{ε1} atom of Tyr190: 3.8 Å). Immediately after binding, GB reorients around its trimethylammonium group to the configuration seen in the closed structure as observed in the MD simulation. This reorientation leads to GB attracting the side chain of Tyr190 and Tyr111. The additional cation- π interactions between Tyr111 and Tyr190 and GB's trimethylammonium group are energetically favorable; their formation may thus be the cause why the domain closure of AfProX is facilitated in the ligand-bound state compared to the unliganded structure as also observed in the MD simulations. The Tyr111 and Tyr190 movements are relayed to Arg149 via the above-described interactions. Ultimately, the reorientation of GB triggers domain closure and induces the high-affine liganded-closed conformation in which Arg149 finally complements and locks the binding site and stabilizes the domain closure (Figure 8C).

During the domain closure, part of the Arg-loop changes from a stable α -helical conformation in the open structure to an unwound conformation in the liganded-closed structure. This secondary structure change leads to a “loaded spring” in this region, which is restrained by a salt bridge of Arg149 (domain II) with the carboxyl group of GB. GB itself forms additional salt bridges with Lys13 and Thr66 of domain I. If this Arg149-GB interaction is disrupted, the Arg-loop will adopt its energetically favored, “relaxed” helical conformation. This leads to the opening of AfProX and, hence, the release of the substrate. As a consequence, AfProX should not bind solutes that lack a carboxyl group, e.g. choline. Furthermore, since the exact positioning of the carboxyl group is important, compatible

solutes with increased size, e.g. crotonobetaine, homobetaine, carnitine, dimethylsulphonio acetate, and ectoine should not induce a stable closed conformation. This is what we observed in competition assays with radiolabeled GB (Figure 1A). Hence, our analysis of the crystal structures of the *AfProX* protein provides a rational explanation for the observed substrate specificity.

Discussion

High-affinity ligand binding by the AfProX SBP

The crystal structures of wild-type AfProX in complex with GB and PB and an open unliganded configuration were previously reported (62). The latter structure is thought to represent the open conformation of AfProX as suggested by the “Venus fly trap model” (48). AfProX exhibits high affinities for its substrates GB ($K_D = 60 \text{ nM} \pm 10 \text{ nM}$) and PB ($K_D = 50 \text{ nM} \pm 10 \text{ nM}$), and it is highly substrate-specific for these two compatible solutes (Figure 1A). GB and PB serve as excellent thermoprotectants (Figure 1B). To our knowledge, thermoprotection of a hyperthermophilic archaeon by GB or PB has never been described before, although both compatible solutes are known to possess thermoprotective properties for mesophilic bacteria (63).

We probed the contribution of individual residues within the substrate-binding site of AfProX to ligand binding and found that single amino acid substitutions within the Tyr cage reduced ligand binding between 60-fold (Tyr214/Ala; $K_D = 3.5 \text{ } \mu\text{M} \pm 0.7 \text{ } \mu\text{M}$) to 2400-fold (Tyr63/Ala; $K_D = 149 \text{ } \mu\text{M} \pm 17 \text{ } \mu\text{M}$). Mutating any two Tyr residues in the aromatic cage to Ala abrogates ligand binding completely (Supplementary Table 1). Similar effects have been observed for the ectoine binding protein EhuB from *Sinorhizobium melliloti* (65), GB/PB-specific OpuAC from *Bacillus subtilis* (66), and ProX from *E. coli* (67). Here, cation- π interactions also contribute strongly to ligand binding.

Switching the AfProX SBP from low to high affinity

In AfProX, Arg149 plays a distinct role in substrate binding as its substitution by an Ala residue results in a loss of binding affinity from $K_D \approx 50\text{--}70 \text{ nM}$ to $K_D \approx 300\text{--}400 \text{ } \mu\text{M}$. In the liganded-open structure, Arg149 is located $\sim 10 \text{ \AA}$ away from its final position in the liganded-closed structure. Hence, the ligand-binding site is laid open, and the substrate has free access to the binding pocket. Our data suggest that Arg149 is the final amino acid to interact with the substrate and, thereby, captures GB or PB in the high-affine closed state of AfProX.

Domain closure triggered by substrate binding

The “Venus fly trap” model describes the opening and closing of SBPs in solution where the equilibrium between these two conformations is shifted towards the closed state upon substrate binding (68). Many crystal structures of SBPs have been solved in the unliganded-

open, liganded-closed, and, more rarely, in the unliganded-closed state (48, 53, 62, 69). In striking contrast, only a few proteins have been crystallized in a liganded-open conformation. Examples are the leucine-isoleucine-valine binding protein (LIV), where the substrate was soaked into preformed unliganded protein (68) and the liganded-open form of MBP (56). In the case of MBP, the non-natural substrate β -cyclodextrin is bound, which is not transported, however (56). In the liganded-open structures of LIV or MBP, the binding site is completely open, and the substrate is bound by amino acids that originate from only one domain of the SBP. In the case of MBP, it was therefore postulated that, first, maltose interacts with the aromatic groups of the C-terminal domain to form a complex with the open form (70). Then, the complex converts into the stable closed conformation of MBP. However, molecular dynamics studies of MBP show that the unliganded protein can adopt a wider variety of conformations than the maltose-bound state, indicating that ligand binding not only affects the relative orientation of the two domains but also attenuates their movement relative towards each other (71). In contrast to the situation described for MBP, we found that the substrate-binding site of AfProX is pre-formed in the open conformation. Thus, only a slight reorientation has to occur to optimize the binding site towards its closed conformation. Still, although the open conformation contains a largely assembled binding site, it exhibits only low binding affinity towards GB or PB. Our mutational analysis of AfProX revealed a distinct role of Arg149 in substrate binding: the movement of this residue, which complements the binding site in the closed AfProX structure, changes AfProX from a low- to a high-affine state by locking the binding site and mediating domain-domain interactions, thus finally trapping the ligand.

Comparison with other SBP

The triggering mechanism that we have observed in AfProX is intriguing and might apply to other SBPs. Therefore, we carefully compared open and closed structures of MBP. Domain I was chosen as anchor point for the super-positioning of both conformations because it shows almost no conformational change in going from the open to the closed state.

The comparison reveals that Met330 undergoes only a relative small movement of 2.5 Å from the unliganded-open to the liganded-closed structure. Like Arg149 in AfProX, Met330 is connected via a network of side chain interactions to all amino acids participating in substrate binding. First, this is achieved through an interaction network of Met330-Tyr155-Glu153-Arg344. Second, Tyr155 interacts with Trp230 and Phe156. The distance between these side chains does not change in the open and closed structures, identical to the observation in AfProX. Hence, the movement of Met330 allows triggering a pushing event towards all amino acids involved in substrate binding in the second MBP domain. In addition to this network, Met330 also interacts with Phe258, which is located at the beginning of a beta

sheet. It has been shown that this beta sheet is important for stabilizing the closed conformation as it contains Gly260, which is part of a salt bridge that is only observed in the closed conformation of MBP (71).

Similar observations have been made when comparing the open and closed structures of the ribose binding protein from *E.coli* (72) as well as the binding protein of the *N*-Acetyl-5-neuraminic acid TRAP transporter from *H. influenza* (73).

Substrate release by external modulation of Arg149 interactions

The Arg-loop of the *AfProX* protein has a α -helical conformation in the open structure. In the liganded-closed structure, however, this helix is unwound. The energetic cost of unwinding this region is diminished by multiple interactions of Arg149 with domain II of *AfProX* and the GB ligand. Furthermore, in the liganded-closed structure of *AfProX*, the side chain of Arg149 is interacting with Glu145, whereas no such interaction occurs in the open structure. Finally, salt-bridge formation between Arg149 and Glu145 upon domain closure is also observed during the MD simulations (see above). Interestingly, Glu145 is exposed at the membrane-facing side of *AfProX*.

Taken together, our data leads us to suggest a model where a conformational change in the membrane components (ProW-1, ProW-2) and the ATPase (ProV) of the ProU ABC transporter from *A. fulgidus* results in the manipulation or even the disruption of the Glu145-Arg149 salt-bridge. This event is expected to loosen the interactions of Arg149 with the GB and PB substrates, which, in turn, would induce a re-formation of the helical conformation of the Arg-loop. Finally, the opening of the binding site of the *AfProX* protein would be triggered. Consequently, the affinity of the substrate-binding site would change from low nM to medium μ M range, which would facilitate release of the ligand into the substrate-translocation pathway for ATP-dependent import into the *A. fulgidus* cell.

In summary, our data suggest that Arg149 acts as a trigger to fulfill the role of *AfProX* in thermoprotection: here, a fast response of the SBP is required to ensure a fast and efficient ligand capture. A preformed ligand-binding site that only requires a single amino acid to switch the system from a low- to a high-affine state is a perfect solution to environmental restraints. Our data implies that distinct molecular events such as single amino acid triggers are overlaid with the "Venus-fly trap" mechanism to ensure the specific biological function of SBPs.

Materials and Methods

Crystallization

AfProX crystals were obtained using the hanging drop method at 293 K against a reservoir solution of 100 mM HEPES pH 7.0, 15-25% PEG6000 and 15-25% PEG 8000. AfProX was incubated with 10 mM glycine betaine prior to crystallization. Crystals grew slowly and appeared after one month. They were flash frozen in liquid nitrogen with mother liquor, supplemented with 20-25% ethylenglycerol as cryoprotectant.

Data collection, refinement and structure analysis

AfProX crystals diffracted X-rays beyond 1.6 Å. However for refinement purposes the dataset was truncated at a resolution of 2.0 Å. The dataset of AfProX was collected at the ID23-EH2 beamline at the ESRF and processed with XDS (74). AfProX in the ligand free form (PDB code: 1SW5) (62) was used as a template to obtain initial phases using PHASER (75). The structure was further refined using REFMAC5 (76) and COOT (77). Dataset and refinement statistics are listed in Table 2 in the Supplementary Information. As analyzed with Procheck (78), the Ramachandran plot of AfProX shows one residue in the disallowed region. However, this residue interacts with the bound HEPES molecule, which explains the rather unusual conformation. Figures of protein molecules were prepared using PyMol (www.pymol.org).

Molecular dynamics simulations

Molecular dynamics simulations were performed with the AMBER 10 suite of programs (79) together with the force field as described by Cornell *et al.* (80) using modifications suggested by Simmerling *et al.* (81). In total, four different MD simulations were performed: I) liganded-open wt AfProX. The starting structure was generated by mutating Ala111 in the crystal structure of Tyr111Ala AfProX to Tyr. The simulation length is 200 ns; II) liganded-open wt AfProX. In contrast to I), a distance restraint by means of a harmonic potential was applied between the ammonium nitrogen of GB and the N of Asp109 of AfProX. The simulation length is 25 ns; III) liganded-closed wt AfProX. The starting structure was taken from PDB code 1SW4 (62). The simulation length is 50 ns; IV) liganded-closed Arg149Ala AfProX. The starting structure was generated from the liganded-closed wt AfProX structure by mutating Arg149 to Ala. The simulation length is 50 ns.

In all cases, the starting structure was placed into an octahedral periodic box of TIP3P water molecules (82). The distance between the edges of the water box and the closest atom of the protein was at least 11 Å, resulting in a system of ~43000 atoms. The system was minimized by 50 steps of steepest descent minimization followed by 450 steps of conjugate

gradient minimization. The particle mesh Ewald (PME) method (83) was used to treat long-range electrostatic interactions, and bond lengths involving bonds to hydrogen atoms were constrained using SHAKE (84). The time-step for all MD simulations was 2 fs, with a direct-space, non-bonded cutoff of 8 Å. Applying harmonic restraints with force constants of 5 kcal mol⁻¹ Å⁻² to all solute atoms, canonical ensemble (NVT)-MD was carried out for 50 ps, during which the system was heated from 100 K to 300 K. Subsequent isothermal isobaric ensemble (NPT)-MD was used for 150 ps to adjust the solvent density. Finally, the force constants of the harmonic restraints on solute atom positions were gradually reduced to zero during 100 ps of NVT-MD. The following NVT-MD at 300 K with a time constant of 10 ps for heat-bath coupling was used for analysis, with conformations extracted every 20 ps. Atomic charges for the GB ligand were generated following the RESP procedure (85); force field parameters for GB were taken from GAFF (86).

For analyzing the trajectories, conformations were superimposed with respect to the C_α atoms of domain I. This resulted in an almost perfect overlay in all cases. Root mean-square deviations with respect to the open or closed starting structures were then determined for C_α atoms of domain II or the atoms of GB.

ACKNOWLEDGEMENTS

We thank the members of the laboratory of L.S. and E.B. for stimulating discussion. We thank Christoph Müller Dieckmann for excellent support at the beamlines of the EMBL Outstation Grenoble (France) as well as Dr. Paul Tucker and Dr. Matthew Groves at the BW7A beamline, EMBL Outstation Hamburg. Financial support for this study was provided by the Fonds der Chemischen Industrie and the LOEWE program of the State of Hessen via the Centre for Synthetic Microbiology [SynMicro; Marburg] to E.B. This work was funded by the consortia – EDICT (European Initiative on Channels and Transporters) FB7 Theme [Health-2007-2.1.1-5 to B.T and L.S.]. HG is grateful to the „Zentrum fuer Informations- und Medientechnologie“ (ZIM) at the Heinrich-Heine-University, Düsseldorf, for computational support.

Figures

Figure 1: AfProX mediated thermoprotection of *A. fulgidus*

A) Substrate specificity of AfProX. The substrate specificity of ProX was investigated in a competitive radioactive binding assay. 5 μ M AfProX in 100 μ l 10 mM Tris-HCl (pH 7.5) were incubated at 85°C with 5 μ M [1-¹⁴C] glycine betaine and forty-fold excess of different unlabeled compatible solutes. As control the same experiment was done with no competitive substrate and that value was set to 100 %. B) Influence of GB and PB on the growth of *A. fulgidus* at elevated temperature. Pre-warmed media lacking or containing 2 mM GB or 2 mM PB were inoculated with 5 % exponentially growing *A. fulgidus* cells and incubated on a rotary shaker at 90°C. Squares: *A. fulgidus* cells grown in the absence of either GB or PB; diamonds: *A. fulgidus* cells grown in the presence of 2 mM GB; triangles: *A. fulgidus* cells grown in the presence of 2 mM PB.

Figure 2: The binding site of Tyr111Ala AfProX

The GB-binding site of Tyr111Ala AfProX is shown in sticks as is Arg149 with its neighboring residues Asp145 and Glu151. Dashed lines depict distances $< 3.5 \text{ \AA}$ between Arg149 and Asp145 or Glu151. Bound GB is highlighted in blue.

Figure 3: Overlay of Tyr111Ala AfProX with the liganded-closed and the unliganded-open structure of AfProX.

A) Overall structure of AfProX highlighted as cartoons. B) Overlay of the Tyr111Ala AfProX structure with the liganded-closed structure of AfProX (pink, PDB code 1SW2). C) Overlay of the Tyr111Ala AfProX structure with the unliganded-open structure of AfProX (light green, PDB code 1SW5). The overlays were calculated using LSQMAN.

Figure 4: Overlay of the Tyr111Ala AfProX binding sites

A) The binding site of Tyr111Ala AfProX (shown in blue) is overlaid with the open unliganded structure (orange). Residues involved in substrate binding are highlighted.

B) The binding site of Tyr111Ala AfProX (shown in blue) is overlaid with the liganded-closed structure (white). Residues involved in substrate binding are highlighted. For simplicity, Asp109 was not included in A and B. We note that this residue superimposes perfectly in both structures.

Figure 5: MD simulation started from the open-liganded wild type AfProX structure tethering GB in the binding site.

A) Rmsd of domain II with respect to the closed-liganded structure (red); rmsd of GB with respect to the starting structure (green); B) rmsd of Tyr 111 and Tyr190 with respect to the closed structure (red); minimal distance between O ϵ atoms of Glu145 and NH atoms of Arg149 (green). The dashed line indicates the simulation time at which the conformation shown in Figure 6 was extracted.

Figure 6: Overlay of the open structure (orange), the closed structure (dark blue), and the conformation extracted after 11 ns from the MD simulation started from the open-liganded wild type AfProX structure, in which GB was tethered in the binding site (cyan).

A) Domain II of the extracted conformation comes as close as 4.2 Å rmsd to the closed structure. B) Close-up view of the tyrosine pocket.

Figure 7: MD simulation started from the closed-liganded AfProX structure for wild type AfProX (red) and AfProXArg149Ala (green).

Rmsd values of domain II with respect to the open AfProX structure are shown.

Figure 8: Proposed mechanism of AfProX during substrate capturing and high affinity binding.

A) The open conformation of the binding site of AfProX is shown. B) The ligand GB is captured and bound in the binding site C) Binding of the substrate triggers closure of the two domains via the Tyr190-Tyr111-Phe146 network. In the closed structure Arg149 interacts with GB (red, dashed line). All highlighted distances (dashed lines) are between 3.2 and 3.8Å

Thermoprotection of *A. fulgidus* by glycine betaine and proline betaine.

In addition to the well-established role of compatible solutes as osmoprotectants (87-89), recent experiments attribute a thermoprotective function to these compounds. Thermoprotection by glycine betaine (GB) has been observed both in bacteria (90, 91) and in plants (92). The hyperthermophilic archaeon *A. fulgidus* can grow in a temperature range from 64°C to 92°C, with an optimal growth temperature of 83°C; this growth behavior was investigated in media containing 0.1% yeast extract (93). Since yeast extract is known to contain GB (94), we wondered whether GB and proline betaine (PB) might serve as thermoprotectants for *A. fulgidus*. The presence of either 2 mM GB or 2 mM PB in a chemically defined medium lacking yeast extract did not have any influence on the growth of *A. fulgidus* at its optimal growth temperature of 83°C (Supplemental Fig. 1). However, this picture changed dramatically when we investigated the growth of *A. fulgidus* at 90°C. In the absence of a compatible solute, *A. fulgidus* was unable to grow at this elevated temperature. In contrast, growth was rescued to a large extent by the presence of either 2 mM GB or 2 mM PB (Supplemental Fig. 1). Consequently, both compatible solutes function as thermoprotectants for the hyperthermophilic archaeon *A. fulgidus*.

Growth at high temperature (90°C) had a noticeable effect on the cellular level of the AfProX protein. In comparison with cells that were grown at 83°C, the amount of AfProX was increased approximately four-fold in *A. fulgidus* cells that were propagated at 90°C.

Determination of the affinity constants of wildtype and mutants of AfProX for glycine betaine and proline betaine.

Binding of GB and PB to purified AfProX influenced the spectroscopic properties of AfProX. Substrate binding of these compatible solutes leads to an increase of the intrinsic tryptophan fluorescence. We exploited this feature to determine the affinity constants (K_D) for both substrates. AfProX binds GB and PB with high affinity, 60 ± 10 and 50 ± 10 nM, respectively (Supplemental Table 1). According to the structure of AfProX (62), it is evident that the substrate binding pocket is built up by four tyrosines (Tyr63, Tyr111, Tyr190, and Tyr214) as well as Lys13, Thr66, and Arg149. To further understand the residues' roles for substrate binding, they were mutated to alanine, and the substrate affinity was measured (Supplemental Table 1). Mutation of any of the four tyrosines reduced the affinity, ranging from 3.5 ± 0.7 μ M for Y214A to 149 ± 17 μ M for Y63A, respectively (Supplemental Table 1). Any one of the double Tyr to Ala mutants was not able to bind GB at all.

The K13A and T66A mutants also showed a lower affinity, 1.8 ± 0.2 μ M and 107 ± 20 μ M, respectively (Supplemental Table 1). The largest decrease in affinity in the case of a single mutation was observed for the Arg149Ala mutation. Here, the K_D drops to 320 ± 60 μ M for GB, and no binding could be observed for PB (Supplemental Table 1). This suggests a specific role of Arg149 in the substrate binding to AfProX.

Crystallographic analysis and overlay

Crystals were grown as described in Material and Methods. A dataset of the AfProX Tyr111Ala in complex with GB was collected at beamline ID-23 (ESRF, Grenoble, France) and processed using XDS (74). Initial phases were obtained by molecular replacement using the program PHASER (75) with the unliganded-open AfProX structure as template (PDB entry: 1SW5) (62). The final structure was refined to a resolution of 2.0 Å. Data, refinement statistics, and model content are summarized in Supplemental Table 2.

Tyr111Ala AfProX adopts the same conformation as the unliganded-open structure, as revealed by a perfect overlay (Figure 2). The RMSD between two open and a closed liganded structure was analyzed by the DYNDOPE server (95). An overall RMSD value of 4.75 Å for all C- α atoms was calculated for the Tyr111Ala structure with respect to the closed-liganded structure (PDB code 1SW2) whereas no significant structural difference was found with respect to the unliganded-open structure (PDB code 1SW5) (RMSD < 0.2 Å).

Material and Methods

Microorganisms. The *Archaeoglobus fulgidus* strain VC16 (DSMZ 4304), whose genome sequence is known (96), was kindly provided by K. O. Stetter (University of Regensburg, Germany). *A. fulgidus* cells were grown anaerobically at 83°C or 90°C in sealed 100-ml serum bottles on a rotary shaker set at 120 rpm. We used the chemically defined medium described by Stetter et al. (93) with slight modifications for the propagation of *A. fulgidus*. The medium contained (per liter) 100 ml salt solution, 10 ml trace element solution, 5.5 g NaHCO₃, 2 mg (NH₄)₂Fe(SO₄)₂ and 10 mmol L-lactate as carbon and energy source. The salt solution contained (per liter) 74 g MgSO₄·7H₂O, 3.4 g KCl, 27.5 g MgCl₂·6H₂O, 1.4 g CaCl₂·2H₂O, 1.4 g K₂HPO₄, 180 g NaCl, and 5 ml Resazurin (0.2% w/v). The trace element solution contained (per liter) 1.5 g Titriplex I, 3 g MgSO₄·7H₂O, 0.01 g NaWO₄, 0.01 g H₃BO₃, 0.01 g Na₂MoO₄·2H₂O, 0.025 g NiCl₂·6H₂O, 0.3 g Na₂SeO₃·5H₂O, 0.45 g MnSO₄·H₂O, 1 g NaCl, 0.1 g FeSO₄·7H₂O, 0.18 g CoSO₄·7H₂O, 0.1 g CaCl₂·2H₂O, 0.18 g ZnSO₄·7H₂O, 0.01 g CuSO₄·5H₂O, and 0.02 g KAl(SO₄)₂·12H₂O. The pH was adjusted to 6.5 with KOH. We omitted the yeast extract from the originally described growth medium (93) because it is known to contain compatible solutes (e.g. GB or PB) (94); the presence of undefined concentrations of compatible solutes in the growth medium would interfere with the growth assays we performed with *A. fulgidus*. Instead, we used a vitamin solution that had the following composition per liter: 2 mg biotin, 2 mg folic acid, 10 mg pyridoxine-HCl, 5 mg thiamine-HCl·2 H₂O, 5 mg riboflavin, 5 mg nicotinic acid, 5 mg D-Ca-pantothenate, 0.1 mg vitamin B₁₂, 5 mg p-aminobenzoic acid, and 5 mg lipoic acid. The medium was adjusted to pH 6.8 with H₂SO₄, evacuated and gassed with N₂:CO₂ (80:20, v/v). After heat sterilization, the medium was reduced by the addition of 0.5 ml 0.5 M Na₂S and 0.5 ml Na₂S₂O₄. The osmolality of the medium was adjusted by the addition of solid NaCl to the indicated final concentrations. For growth experiments, the pre-warmed (83°C) medium was inoculated with 5 % of exponentially growing cells of an *A. fulgidus* pre-culture, and growth of the cells was monitored by determining the total cell number with a Helber counting chamber under a phase contrast microscope.

Chemicals. GB, choline, carnitine, proline, monomethylglycine, and dimethylglycine were purchased from Sigma (Deisenhofen, Germany). PB (stachydrine-HCl) was obtained from Extrasynthese (Genay, France). Ectoine was purchased from BIOMOL (Hamburg, Germany), and dimethylsulfoniumpropionate (DMSP) was a kind gift from T. Hansen (University of Groningen, the Netherlands). Radiolabeled [1-¹⁴C] glycine betaine (55 mCi mmol⁻¹) was purchased from American Radiolabeled Chemicals Inc. (St. Louis, Mo., USA). Factor Xa was obtained from New England Biolabs (Schwalbach, Germany). Desthiobiotin was purchased from Sigma (Deisenhofen, Germany).

Methods used with nucleic acids and plasmid construction. To construct an expression plasmid carrying the *AfProX* gene with an N-terminal Strep-Tag affinity peptide, we amplified the *proX* gene with the oligonucleotides 5'-AAAAAAGGGCTCCAGCGCGGTCCCAATCATCTGAGAG-3' and 5'-AAAAAAGGGCTCCATATCATTAAACGAGTCCCTGCTCCT-3' by PCR using chromosomal DNA of *A. fulgidus* VC16, kindly provided by S. Shima (Max-Planck Institute for Terrestrial Microbiology, Marburg, Germany). The PCR-product was digested with *Bsa*I and cloned into the expression vector pASK-IBA6 (IBA, Göttingen, Germany). This construction removed the putative signal sequence of *AfProX* and also mutated the N-terminal cysteine residue into a glycine residue. The sequence of the *A. fulgidus ProX* gene in pGH26 was verified by DNA sequence analysis.

Heterologous expression and purification of AfProX. *AfProX* was heterologously overexpressed using the *E. coli* strain BL21 Codon Plus RIL strain. A ten-liter glass flask containing five liters of MMA supplemented with 150 $\mu\text{g ml}^{-1}$ of ampicillin, 30 $\mu\text{g ml}^{-1}$ chloramphenicol, 0.5% glucose and 0.2% casaminoacids were inoculated to an OD₅₇₈ of 0.1 from an overnight culture. Cells were grown at 37°C with vigorous stirring until the culture had reached OD₅₇₈ = 0.6 - 0.7. Then expression was induced by the addition of anhydrotetracycline (final concentration 0.2 $\mu\text{g ml}^{-1}$). Cells were grown for an additional two hours and were subsequently harvested by centrifugation (10 min, 3000 x g). To release the periplasmic proteins the cell paste was resuspended in 50 ml ice cold buffer P [100 mM Tris-HCl (pH 8), 500 mM sucrose and 1 mM EDTA]. After a 30-minute incubation on ice, the periplasmic protein extract was harvested by centrifugation (15 min, 21000 x g at 4°C), followed by an ultra-centrifugation step (30 min, 120000 x g at 4°C) to remove insoluble material. The supernatant was then loaded onto a 10-ml Strep-tactin column (IBA, Göttingen, Germany) equilibrated with buffer W [100 mM Tris-HCl (pH 8)]. The column was washed with five column volumes of buffer W, and bound proteins were released from the affinity resin by washing the column with buffer E [100 mM Tris-HCl (pH 8), 2.5 mM desthiobiotin]. Since a portion of the pro-OmpA signal sequence was not proteolytically removed from the ProX protein by the *E. coli* cells, the purified ProX protein was cleaved with factor Xa (1 μg factor Xa per 200 μg ProX) for 16 hours at room temperature in a buffer

containing 100 mM Tris-HCl (pH 8), 100 mM NaCl, and 1 mM CaCl₂. This proteolytic cleavage removed the OmpA signal sequence and the Strep-Tag sequence, thereby resulting in AfProX containing no N-terminal extensions. To remove factor Xa from the solution, the protein solution was diluted 1:2 with deionized water and loaded on a UnoQ6 column (BioRad, Muenchen, Germany) equilibrated with 50 mM Tris-HCl (pH 8) (buffer A). The column was washed with 20 ml buffer A, and the protein was eluted with a linear NaCl gradient. AfProX eluted at 250 mM NaCl. AfProX was subsequently dialyzed overnight against five liters of 10 mM Tris-HCl (pH 7.5) at 4°C and stored until further use at 4°C. In general, 2 mg of pure AfProX protein were obtained per one liter of overproducing cells.

Substrate binding of purified AfProX.

To study substrate binding properties of AfProX, we used the ammonium sulfate precipitation technique of Richarme and Kepes (97). 5 μM of AfProX were incubated at 85°C (or at other temperatures as indicated) with 5 μM [1-¹⁴C] glycine betaine in a volume of 100 μl 10 mM Tris-HCl (pH 7.5) for 5 minutes. AfProX was then precipitated by the addition of 900 μl of an ice-cold saturated ammonium sulfate solution. After a 5-minute incubation on ice, the mixture was sucked through cellulose filters (0.45 μm pore size, Scheicher and Schuell, Dassel, Germany), and the radioactivity retained by the filters was determined by liquid scintillation counting. To determine the substrate specificity of AfProX, the protein was incubated at 85°C with 5 μM radiolabeled glycine betaine and a forty-fold excess of different unlabeled compatible solutes and was further treated as described.

Determination of the binding affinity (K_D) of AfProX using fluorescence spectroscopy.

All spectra were obtained at room temperature with a VARIAN CARY Eclipse fluorometer (VARIAN, Darmstadt, Germany). Emission scans were collected at an excitation wavelength of 280 nm from 290 nm to 450 nm. Measurements were carried out in 1 ml 10 mM Tris-HCl (pH 7.5). 5 μg of AfProX protein were added to the buffer, and the solution was mixed. To titrate the protein, 5 μl substrate was added from a 40 μM GB or PB stock solution. After substrate addition, the sample was mixed in the cuvette and the change in the fluorescence was

recorded. This step was repeated until a stable fluorescence signal was obtained. Assuming one binding site per monomer in AfProX, the K_D for substrate binding was determined by nonlinear least-squares fitting of the data to the following equation: $F = F_0 + (DF/2P_0) \left[(K_D + P_0 + L_0) - \left((K_D + P_0 + L_0)^2 - 4L_0P_0 \right)^{1/2} \right]$. F is the measured fluorescence; F_0 the fluorescence of AfProX; DF is the change of fluorescence at saturation; P_0 and L_0 are the total concentrations of protein and substrate.

Isothermal titration calorimetry. ITC was performed using an ITC200 calorimeter from Microcal Inc. (GeHealthcare) at 50°C. Protein concentration was 10 μ M in 20mM Tris pH 7.0, 20mM NaCl. The titration syringe was loaded with 50 μ M glycine betaine prepared from the same solution as the protein. Titrations were usually carried out using 72 injections of 0.5 μ l each at 160 s intervals. Stirring was set to 350 rpm. Data were corrected for heats of dilution by subtracting a blank titration, acquired by injecting an equal amount of ligand into buffer.

Substrate triggered domain closure in other SBPs

In the ribose binding protein (RBS) the substrate is bound by several amino acid of both domains (72)..Here again the superimposition of the open and the closed structure revealed a perfect overlay of the amino acids located in domain I. In domain II however the AA undergo a significant movement. Here a network was identified via the side chain of Gln235, which during closing undergoes a small conformational change of 1.5Å. The network can be described as follows: Gln235-Phe15-Phe16-Asn64-Arg90-Asp89. The Gln235 is located directly at the hinge between both domains which explains the small movement.

Siap is the binding protein of the N-Acetyl-5-neuraminic acid TRAP transporter from *H. influenza* (73). Here a specific role can be assigned to Arg127. Besides interacting with the substrate in the closed conformation a side chain interaction network can be observed via interactions with Pro149 and Asn187. Asn187 itself is in contact with Phe170 and Arg147, which all together build up the substrate-binding site in SIAP of domain II. Here as well as in MBP and RBS the distances in this network do not change in the open and closed form of the structures. In SIAP Arg127 has been mutated to alanine as well as Lysine. In elisa competitions

assays the function of SIAP has altered for the mutants. Furthermore no binding of substrate to the R127A mutant could not be observed anymore by using ITC, which is explainable by the proposed specific role of Arg127 in domain closure (73, 98).

Legends

Table 1: Mutational analysis of the binding site of AfProX.

The affinity of wild type AfProX and AfProX mutants are listed for GB and PB. No binding for any of the double mutants was observed; hence, these mutants are not listed in the table. n.b. indicates that no binding was observed under this experimental setup.

Table 2: Crystallographic parameters.

Crystal parameters and data collection statistics are derived from XDS (99). Refinement statistics were obtained from REFMAC5 (76). Ramachandran analysis was performed using PROCHECK (100, 101). ^a R_{sym} is defined as $R_{sym} = \frac{\sum_{hkl} \sum_i |I_i(hkl) - \langle I(hkl) \rangle|}{\sum_{hkl} \sum_i I_i(hkl)}$ and ^b R_F as $R_{sym} = \frac{\sum_{hkl} \sum_i |I_i(hkl) - \langle I(hkl) \rangle|}{\sum_{hkl} \sum_i I_i(hkl)}$. R_{free} is calculated as R_F but for 5% randomly chosen reflections that were omitted from all refinement steps.

Table 3: Summary of the interactions of domain I and domain II in the closed form of AfProX.

Suppl Figure 1: Influence of glycine betaine on the growth yield of *A. fulgidus*

A) *A. fulgidus* was grown in a defined minimal medium lacking yeast extract without (•) or with 2 mM GB (◐) at different salt concentrations. Growth yields of the various cultures were monitored after 20 hours by counting the total cell number in a Helber counting chamber under a phase contrast microscope.

B) Pre-warmed media (83°C) lacking or containing 2 mM GB or 2 mM PB were inoculated with 5 % exponentially growing *A. fulgidus* cells and incubated on a rotary shaker at the indicated temperatures. Growth was monitored over time by counting the cell number with a Helber counting chamber under a phase contrast microscope. Squares: *A. fulgidus* cells grown in the absence of both GB and PB; diamonds: *A. fulgidus* cells grown in the presence of 2 mM GB; triangles: *A. fulgidus* cells grown in the presence of 2 mM PB.

ABSTRACT

Determination of the critical micelle concentration (CMC) value of detergents routinely used in biological applications is necessary to follow possible changes due to different buffer compositions (e.g., temperature, pH) such as those in solutions that are used for protein activity assays or crystallization. Here we report a method to determine the CMC values of detergents through a fast and robust assay that relies on the fluorescence of Hoechst 33342 using a 96-well plate reader. Furthermore, this assay provides the possibility and sensitivity to measure the CMC of detergent mixtures. The examples described here emphasize the potential and applicability of this assay and demonstrate that analysis of the physicochemical parameters of detergents can now be investigated in virtually every laboratory.

Facing the fact that the “-omics” era has reached nearly every branch of natural, life, and medical sciences, new techniques often must prove their potential for handling an enormous number of samples or experimental conditions that need to be screened during the quest to find the right conditions for one-pot synthesis, drug–protein interactions, crystallizing proteins, and the like.

Genome projects estimate that roughly 30–40% of all proteins encoded in the human genome are membrane-embedded or membrane-associated proteins (MPs)⁴ [1,2]. In addition, MPs account for approximately 70% of all drug targets [3]. Therefore, it is of great importance to describe MPs functionally and structurally. A major obstacle is to solubilize MPs from their native environment, the lipid bilayer, in a functional form. To overcome this intrinsic problem, a huge variety of biologically important detergents have emerged, and new ones are being constantly synthesized to match the ambitious needs of biochemists and medicinal pharmacologists [4]. The solubilization of MPs is not the only critical procedure, also subsequent steps

such as purification, dialysis, concentration, biochemical assays, and crystallization are performed in the continuous presence of detergents and numerous additives specific for the desired experiment [5–7]. These additional substances (e.g., salt, glycerol, buffer, metal ions, sugars) as well as physical parameters (e.g., pH, temperature) influence the critical micelle concentration (CMC) of detergents. Because detergents prevent MPs from aggregation, precise knowledge of the detergent concentration and its CMC at a given experimental condition may become crucially important. Most MPs lose their activity when the detergent concentration drops below the CMC, and because too high detergent concentrations can induce protein unfolding and disrupt protein–protein interactions, this can hinder protein activity and crystallization. Therefore, it can be crucial to minimize the detergent concentration, which requires detailed knowledge of how the experimental conditions affect the detergent's CMC.

Different methods to determine the CMC and concentrations of detergents already exist, including fluorescence techniques [8], infrared spectroscopy [9], thin layer chromatography [10], colorimetric assays [11], and refractive index measurements [12]. However, most of these experimental setups are either not accessible to laboratories working with MPs or not very well suited for higher throughput screening if one considers the amount of material that is needed.

Therefore, we developed an easy-to-use, robust, and fast assay for the determination of the CMC value of detergents routinely used in biological applications that makes it possible to determine the CMC of different buffer compositions such as those in solutions that are used for protein crystallization. The assay is based on the dye Hoechst 33342, which displays literally no fluorescence in hydrophilic environments but emits efficiently in hydrophobic environments.

Materials and methods

Materials: Chemicals and detergents

All chemicals were purchased from Sigma–Aldrich at the highest purity available. Dodecyl maltoside (DDM) was obtained from Glycon Biochemicals (Luckenwalde, Germany). FosCholine 14 [FC-14: 1-myristoyl-2-hydroxy-*sn*-glycero-3-phospho-(1'-*rac*-glycerol)] and FosCholine 16 [FC-16: 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phospho-(1'-*rac*-glycerol)] were purchased from SynphaBase (Pratteln, Switzerland). All other detergents used in this study were obtained from Anatrace (Maumee, OH, USA).

Methods

Fluorescence spectroscopy

To determine the CMC, various detergents were titrated into a fluorescence cuvette from a stock solution. The cuvette contained either double-distilled H₂O (ddH₂O, Milli-Q grade, 0.45 μm filter sterilized) or buffer (50 mM Hepes [pH 7.2] or 50 mM Na–phosphate supplemented with 50 mM NaCl and 5% [w/v] glycerol) supplemented with 7 μM Hoechst 33342. The detergent stock solution also contained 7 μM Hoechst 33342 to circumvent dilution of the fluorescent dye. The resulting fluorescence was measured on a Horiba–Jobin–Yvon Fluorolog 3 spectrophotometer with λ_{ex} = 355 nm and λ_{em} = 457 nm (λ_{em} = 487 nm for perfluorooctanoic acid [PFO]), and the slit widths were 2 and 1 nm, respectively. Data points were recorded until a mean standard deviation below 0.5% was reached. To transfer the method of CMC determination via Hoechst 33342 to a less laborious and time-consuming setup, we used 96-well plates suitable for fluorescence spectroscopy (Greiner Bio-One, FIA plate, black, flat bottom, medium binding), pipetted up to 80 different concentrations for each detergent (this step can also be automated by a pipetting robot) into 96-well plates, and recorded emission spectra (filters used: λ_{ex} = 355 ± 10 nm, λ_{em} = 460 ± 80 nm, BMG Labtech, Offenburg, Germany). Data recorded from the Fluorolog 3 and plate reader gave virtually identical results (Table 1). Fluorescence data were background corrected and analyzed according to Eq. (1) using Prism (version 5, GraphPad, San Diego, CA, USA):

$$F = \frac{F_{\max}([\text{Det}] - \text{CMC})}{(K_{0.5} - \text{CMC}) + ([\text{Det}] - \text{CMC})} \quad (1)$$

where F is the measured fluorescence, F_{\max} is the maximal fluorescence, $[\text{Det}]$ is the absolute detergent concentration, $K_{0.5}$ is the midpoint of the fit function, and CMC is the critical micelle concentration of the detergent, which is determined by the fit.

dn/dc Measurements

We determined the dn/dc values for certain detergents (Triton X-100, DDM, and PFO) and compared these values with data found in the literature (see, e.g., <http://www.affimatrix.com/estore>). In brief, 1 ml of a stock solution of 0.25 g/ml Triton X-100, 1 g/ml DDM, and 0.25 g/ml PFO was injected in appropriate dilutions via the direct injection mode into an optiLAB rex (Wyatt Technologies, Santa Barbara, CA, USA). Refractive index measurements were used to calculate dn/dc values from peak area versus sample concentration at fixed sample volume (optiLAB rex). The dn/dc values were used to calculate micelle size/mass from subsequent light scattering experiments.

Multiple angle light scattering

To measure micelle size, we used a multiple angle light scattering (MALS) setup miniDAWN Treos/optiLAB rex (Wyatt Technologies) connected to an Äkta Purifier (GE Healthcare, Freiburg;

Germany) using either a Superose 6 or a Superdex 200 10/300 analytical size exclusion column. Here 200 μl of a detergent solution (5% [w/v] DDM, 2% [w/v] FC-16, 5% [w/v] Triton X-100, and 30% [w/v] PFO) was applied onto the column. The flow rate was 0.2 ml/min. Ultraviolet (UV) detection was at 280 nm, light scattering was detected at angles of 0°, 90°, and 107°, and the obtained values were averaged. MALS data were evaluated using the program ASTRA (Wyatt Technologies). For PFO, the micelle size could not be determined reliably. Due to its surface properties inherent to perfluorinated substances, PFO interacted intensively with the column material. Using an asymmetric flow field–flow fractionation setup (Eclipse AF4, Wyatt Technologies) connected to a MALS detector, no conclusive results could be produced because the detergent seemed to interact with the membrane and the Teflon fittings.

Measurements of detergent mixtures

To measure the CMC values of detergent mixtures, we applied the same methodology used for the determination of CMC values of single detergents. In the examples presented here, the wells of a 96-well plate were preloaded with FC-16, decyl maltoside (DM), and β-octylglucoside (β-OG) at half the CMC and then were titrated with either DDM, DM, or β-OG, and the fluorescence of Hoechst 33342 was measured as described above.

Results

Determination of the CMC and comparison of CMC value derived from plate reader and Fluorolog measurements

In ddH₂O, aqueous buffers, and buffers containing detergents below the CMC, no (or only marginal) Hoechst 33342 fluorescence can be detected. On constant increase of the concentration of detergent, the CMC value will be reached and micelles start to form. As soon as this point is passed, micelles begin to incorporate Hoechst 33342, which can be monitored by an increase of the fluorescence signal (shown schematically in Fig. 1). This point represents the CMC of the detergent (see Ref. [13] and references cited therein). The assay described here is optimized for 96-well fluorescence plates, and data can be evaluated with a plate reader (i.e., enzyme-linked immunosorbent assay [ELISA] reader) available in nearly every laboratory working with membrane proteins.

Formation of micelles was followed by the emitted fluorescence of Hoechst 33342 (emission wavelength 457 ± 10 or 487 ± 10 nm [only in the case of PFO] and 460 ± 40 nm for the Fluorolog 3 and plate reader setups, respectively). We obtained the CMC values for the detergents shown in Table 1 in 50 mM Hepes (pH 7.2), 50 mM NaCl, and 5% (w/v) glycerol except for PFO. This detergent precipitated in Hepes buffer and was dissolved in NaP_i or ddH₂O. The higher sensitivity of the Fluorolog 3 setup allowed us to thoroughly compare the data with data from the plate reader. Table 1 and Fig. 2 clearly indicate that both approaches yielded highly similar CMC values. Therefore, we propose that the 96-well plate reader setup is perfectly suited to accurately determine the CMC value of detergents.

At saturating concentrations, different detergents result in different fluorescent signals (e.g., Triton X-100 and DDM in Fig. 2). This difference most likely results from the different environments that the dye encounters in the core of the micelles and could be used to characterize detergent micelles even further.

Table 1

Comparison of CMC values of different detergents obtained by the Hoechst 33342 or ANS assay and literature values.

Detergent	CMC value Hoechst 33342 (% w/v) (Plate reader)	CMC value Hoechst 33342 (% w/v) (Fluorolog)	CMC value ANS (% w/v) (Plate reader)	CMC value (% w/v) (Literature)	Aggregation number (Literature)	Aggregation number (MALS)

Note. Literature values were taken from <http://www.affimatrix.com/estore>. Errors reported are standard deviations determined by Eq. (1). n.d., not determined; CyMal7, 7-cyclohexyl-1-heptyl-β-D-maltoside.

^a Measured in ddH₂O.

Salt dependency of CMC

It is known that ionic strength can influence the CMC of certain detergents (see, e.g., Ref. [14]). Therefore, we performed experiments to address the question of whether or not our assay can be used to analyze the influence of ionic strength on the CMC value. For DDM, a detergent routinely used for MP purification and crystallization, we showed that micelle formation depends on salt concentration (Fig. 3A). In addition, a great impact on the CMC value in the presence of buffer/salt is shown for PFO (0.8% in ddH₂O vs. 0.2% in buffer). Increasing the NaCl concentration from 0 to 1 M decreased the CMC of DDM nearly fourfold (Fig. 3A). The largest change (twofold) was observed from 0 to 200 mM NaCl, whereas a nearly linear decrease of the CMC value was detected in the case of further increases up to 1 M NaCl (overall twofold change). For PFO, we compared the change of the CMC between ddH₂O and a buffer (50 mM NaP_i, 50 mM NaCl, and 5% [w/v] glycerol) (Fig. 3B). Again, a nearly fourfold reduction of the CMC was observed. The slope of the linear regression of the CMC versus NaCl concentration reflects changes in the strength of self-interaction of the detergent molecules [15]. For the anionic detergent PFO, the observed slope is steeper than that observed for DDM, a non-ionic detergent. This indicates that the self-association of PFO depends stronger on changes of the ionic strength than that of DDM. In addition, the CMC of DDM was not strictly linearly dependent on the NaCl concentrations. This is likely due to different

interactions of the hydrophilic and hydrophobic parts of the detergent in the absence or presence of salt. However, a more detailed analysis would be required to determine the exact nature of this deviation. Nevertheless, these results demonstrate the capability of our assay to easily analyze the influence of certain physicochemical parameters on the CMC of the detergent.

dn/dc values and MALS

We determined the dn/dc values (data not shown) and micelle sizes for the detergents shown in Fig. 2 for cross-validation of our results. From light scattering experiments, the molecular mass of detergent micelles was calculated to be 88 kDa for Triton X-100, 76 kDa for DDM, 80 kDa for FC-16, and 47.4 kDa for polyoxyethylene(8)dodecyl ether (C₁₂E₈) (Fig. 4). These numbers are in good agreement with literature values (Table 1).

Mixed micelles

An interesting observation is that crystal quality of MP can improve dramatically when a second detergent is added. A recent article nicely described the purification and crystallization strategies of the Na⁺-H⁺-antiporter NhaA from *Escherichia coli*, and the authors assumed that the mixture of detergents used improved crystal contacts, allowing a subsequent structure determination [16]. Employing our assay, we showed that detergent mixtures have different CMCs (Fig. 5). For example, when titrating DDM to a solution containing FC-16 at half CMC, micelles formed at a concentration of DDM below the CMC of 'pure' DDM. This is indicative of the formation of mixed micelles [17–19]. In addition, we observed that identical concentrations of FC-16 resulted in higher fluorescence in the presence of DDM, likely due to the formation of a higher number of (mixed) micelles. A similar behavior could be observed for a mixture of detergents with a rather detergents with large CMC value, such as DM and β-OG, or a mixture of detergents with large and small CMCs (DDM and DM [data not shown]).

After solubilization of a MP from a lipid bilayer, detergent micelles mimic the hydrophobic environment of its transmembrane region. Because the transmembrane regions of MPs from different organelles/species can differ greatly in their hydrophobic length [20], the simultaneous use of two detergents with different aliphatic chains is more likely to overcome the problems due to a hydrophobic mismatch such as the lack of crystallization [16] or loss of protein activity. This highlights the importance of a systematic analysis of detergent mixtures.

Fig. 1. Model of micelle formation and the Hoechst 33342-dependent assay. Below the CMC, only detergent monomers are present in solution and no fluorescence of Hoechst 33342 (pale red square) is measured (A). When the detergent concentration increased and reaches the CMC, micelles form and provide a hydrophobic environment for Hoechst 33342, resulting in its fluorescence (deep red square). This point can easily be determined using the assay presented in this study (B). Increasing the detergent concentration will increase the concentration of micelles while the concentration of detergent monomers remains constant. Under saturating conditions, newly formed micelles are not saturated with Hoechst 33342 anymore, and no further increase in fluorescence can be detected (C). (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

Fig. 2. CMC determination of DDM, Triton X-100, and FC-16 via a 96-well plate reader setup (left panels). Data were analyzed according to Eq. (1) (see Materials and methods). The determined CMC values for these and further detergents are listed in Table 1. The difference in maximum fluorescence between for example DDM and FC-16 is likely due to local environmental effects on the Hoechst 33342 fluorescence such as local pH, water penetration, and hydrophobicity of the detergent. A zoom-in of the CMC region of the detergents is shown in the right panels.

ANS measurements

We also performed the experiments using 8-anilino-naphthalene-1-sulfonate (ANS). ANS has been used extensively as a reporter dye to examine the CMC (see, e.g., Ref. [8]). Our results obtained by ANS measurements vary in the range of 1.3–2.0 times the literature values for the CMC with the exception of $C_{12}E_8$, which fit nicely to the literature values (Table 1). We stress that our analysis with ANS is not sufficient to provide an explanation for this behavior. However, the data clearly demonstrate that the assay is not restricted to Hoechst 33342, and if needed other dyes specifically adapted to particular detergent characteristics (e.g., pH, redox sensitivity) might be employed.

Influence of major precipitants on CMC

The crystallization of proteins depends strongly on precipitant solutions that, in most cases, are directly mixed with the protein/detergent solution. Therefore, we also examined the influence of some precipitants routinely used to screen for crystallization conditions (e.g., polyethylene glycol [PEG], 2-methyl-1,3-propanediol [MPD]) on the CMC with the Hoechst 33342 assay. The CMC value increases in the presence of precipitants (Table 2). At higher concentrations of precipitants, the CMC can no longer be determined because the fluorescence values seem to

scatter around a midpoint. In addition, the maximum fluorescence is decreased in comparison with a buffer–detergent mixture that contains no precipitants.

Protein–detergent mixtures

From the fluorescence intensity, it is also possible to determine the detergent concentration of a certain sample so long as the buffer composition does not differ from the control measurement (see experiments shown in Fig. 2). One issue during the purification of MPs is that filtration techniques that concentrate the MPs can also result in a potentially detrimental increase in detergent concentration. We purified a MP via affinity purification (details of expression and purification of the MP will be provided elsewhere). Prior to the measurements, the MP was further purified by size exclusion chromatography in a buffer containing 0.02% DDM. This detergent–MP mixture was then split into three identical aliquots. The first aliquot was mixed with 7 μ M Hoechst 33342, and the resulting fluorescence was directly determined (Fig. 6, left bar). The other two aliquots were concentrated by a factor of 2 using either a 30-kDa or 100-kDa molecular weight cutoff (MWCO) membrane and subsequently diluted back to their original volume with the original buffer and, hence, back to the initial MP concentration. Then 7 μ M Hoechst 33342 was added to both samples, and the corresponding fluorescence values were

Fig. 3. Salt dependency of the CMC of DDM (A) and PFO (B). Decreasing concentrations of DDM or PFO are required for the formation of micelles if the ionic strength of the solution is increased. Straight lines show the linear regression of the data. The dependence of the CMC of PFO in dependence of ionic strength shows a clear linear behavior (black line), whereas a discrepancy is visible in DDM (black line). However, for ionic strengths nonequal to zero, a linear dependency is present (dashed line).

measured (Fig. 6, middle and right bars). An increase of fluorescence as compared with the original mixture would indicate that the detergent-to-protein ratio increased upon concentration; in other words, more detergent molecules are present per MP molecule in the concentrated sample. The back-diluted concentrate from the 30-kDa MWCO membrane exhibited a significantly higher fluorescence than the back-diluted 100-kDa concentrate or the nonconcentrated sample. This indicates that even empty micelles are concentrated on a 30-kDa MWCO concentrator. Thus, our assay can be used to choose suitable concentrators and, thereby, to avoid a potentially deleterious increase of detergent concentration on protein concentration.

Discussion

We have developed an easy-to-use and robust assay to determine the CMC of detergents by Hoechst 33342 fluorescence (Fig. 2). Different kinds of influences on the CMC of detergents can be investigated without the need for highly sophisticated experimental setups. The behavior of the detergents under various conditions, including increasing or decreasing salt concentrations (Fig. 3), high or low pH values, temperature, and additives such as precipitants (Table 2), ligands, and cofactors, can be easily followed and may give valuable hints for adjusting the experimental conditions.

Highly sophisticated and reliable approaches, such as nuclear magnetic resonance (NMR), small angle X-ray/neutron scattering (SAXS/NS), and contact angle measurements, will result in similar values to those with the method described here. But most of the time, relative changes of the CMC due to changes in temperature, buffer composition, or additives are the focus. Our method provides a fast and robust way to analyze such changes.

Fig. 4. MALS combined with size exclusion chromatography for C₁₂E₈ (A), DDM (B), FC-16 (C), and Triton X-100 (D) solutions. To determine the molecular masses of the corresponding detergent micelles, dn/dc values were determined by refractive index measurements (see Materials and Methods for further details).

We also investigated the potential application of the assay on MP preparations that helps to choose suitable protein concentrators and to avoid a potentially harmful increase of detergent concentration. It must be stressed that the MP by itself very likely affects the fluorescence of Hoechst 33342; therefore, an absolute

Fig. 5. Analysis of detergent mixtures. (A) FC-16 was supplied at a concentration of $0.5 \times$ CMC, and DDM was added stepwise (gray squares). The resulting fluorescence curve and the CMC determined from the titration experiments showed small but significant changes compared with that of pure DDM (black squares). (B) When using detergents with a higher CMC (DM and β -OG), mixed micelles were also observed. The CMC value of pure DM (0.087%) is shifted toward larger values in the presence of β -OG (left panel). The same behavior was observed for the inverse experiment (right panel).

Table 2
Influence of precipitants on CMC values of β -OG and DDM.

Detergent	Precipitant	CMC value (% w/v) (Plate reader)
DDM	Buffer	0.0078
DDM	Jeffamine-M600 (10%)	0.0089
DDM	MPD (5%)	0.0087
DDM	MPD (10%)	0.0055
DDM	PEG400 (10%)	0.0082
DDM	PEG400 (20%)	n.d.
DDM	PEG8000 (7%)	0.0099
DDM	PEG8000 (14%)	n.d.

Note. n.d., not determined (for high concentrations of high-molecular-weight precipitants such as PEG4000, a determination of the CMC was not possible due to random scattering of the obtained fluorescence values).

quantification of the detergent concentration in the presence of an MP is not possible. The Hoechst 33342 fluorescence of a detergent-MP mixture arises from three different sources that cannot be separated: binding to empty detergent micelles, to MP-detergent micelles, and directly to the MP. However, changes in detergent concentration are detectable when the concentration of the MP is kept constant (Fig. 6).

In summary, the described method has proven to be a valuable tool for addressing questions arising in all areas of research dealing with detergents. Transfer into a 96-well plate format and the striking simplicity make this method suitable to follow (bio)physical questions that were not easy to address before. We are convinced that on the basis of this assay, further developments will be achieved to investigate different parameters of detergent/detergent-protein complexes and will add an auxiliary biochemical "tool" for membrane protein research.

Fig. 6. Analysis of relative changes in the detergent-to-protein ratio in MP preparations (here shown for DDM). Left bar: Hoechst 33342 fluorescence at an MP concentration of 0.5 mg/ml in 0.02% DDM; middle bar: Hoechst 33342 fluorescence after the preparation was concentrated twofold with a spin concentrator using a 30-kDa MWCO membrane and subsequently diluted twofold with buffer containing 0.02% DDM to the original MP concentration (0.5 mg/ml); right bar: Hoechst 33342 fluorescence after the preparation was concentrated twofold with a spin concentrator using a 100-kDa MWCO membrane and subsequently diluted twofold with buffer containing 0.02% DDM to the original MP concentration (0.5 mg/ml). Error bars represent the standard deviations of five independent measurements.

Abstract

A simple, reliable and fast method for the analysis of detergent containing buffer systems is presented. It enables the determination of CMC values and aggregation numbers of detergents as well as detergent mixtures in 96well plate standard device relying on steady state fluorescence and fluorescence quenching. To prove the universal applicability we demonstrate DDM and mixtures at different ratios with six other detergents.

Abbreviations

CMC: critical micellar concentration; DDM: Dodecyl-maltoside; DM: decyl-maltoside; FC-14: 1-myristoyl-2-hydroxy-sn-glycero-3-phospho-(1'-rac-glycerol); MP: membrane protein; OG: octylglucoside; LDAO: lauryldimethylamine oxide; SDS: Sodium dodecyl-sulfate; SAXS: small angle X-ray scattering; SANS: small angle neutron scattering

Introduction

Analyzing membrane proteins (MP) *in vitro* requires usage of detergents. Initially, MPs are solubilized from cellular membranes and further purified until biochemical, biophysical or even structural studies can be performed. Every of these steps requires a stable and homogenous protein in detergent solution. Often not a single detergent is used for all intermediate steps, in some cases the detergent is exchanged during purification or even detergent mixtures are used to keep the MP in solution. Another pitfall lies within the physical behavior of detergents in buffers or under ionic strength (36, 102). For example, the critical micellar concentration (CMC) differs for DDM in a buffer with no salt compared to a 250 mM sodium chloride solution. Although and in comparison to other detergents, the change of the CMC for DDM from 0.12 to 0.098 mM is rather small (36), the effect of salt on a solution containing more than one detergent is even more complicated and can *a priori* not be estimated.

How crucial the choice of the "right" detergent can be, shows the example of Ca²⁺-ATPase from *Sarcoplasmic Reticulum*. For this membrane protein more than 30 detergents have been tested for preserving the activity of this MP. The analysis focused on chain length, influence of double bonds and character of the head group. A reduced activity was observed for shorter chain length (<10 C-Atoms) and bulky head groups just to mention two examples of this study (103).

Optimal detergent (or detergent mixture) conditions cannot be predicted and an analysis is needed for every single MP or purification step individually. Due to the hydrophilic and hydrophobic part of a membrane protein the exact size of the detergent micelle can play a crucial role for any experiment scheduled after the MP has been purified.

An example for such a screening procedure was described for the crystallization of the Na⁺/H⁺ antiporter NhaA from *E. coli* (104). Here, 14 different detergents were screened in the crystallization process yielding different crystal forms resulting in varying quality of X-ray diffraction of the corresponding crystals. Finally, a mixture of α -dodecylmaltoside (DDM) and β -octyl-glucoside (OG) yielded the best diffracting crystals. The author's assumption is that

the addition of β -OG to NhaA purified in α -DDM reduced the micelle size thereby allowing the formation of stable crystal contacts (104). This phenomena has been suggested as a general strategy for the crystallization of membrane proteins (for other examples see also (105, 106)).

Here, we present a simple 'tool-box' combining different, already published procedures (36, 38-40) to determine the CMC values as well as the aggregation numbers of detergent mixtures. As representative detergent we choose DDM as this is the most widely used detergent in membrane protein purification, analysis and crystallization.

Several studies have shown that pyrene quenching is suitable to determine aggregation numbers of detergents (38, 39, 107-109). However, in most biochemical laboratories this is not commonly used, because these methods are time consuming and require high sophisticated fluorescence equipment. With our method - using 96well standard microtiter plates - it is possible to analyze most properties of the detergent micelles in any buffer system. This can be very valuable information for example when screening for a reduced micelle size, or the amount of free detergent in only a couple of hours.

Materials and Methods

Triton X-100, LDAO and Pyrene were purchased from Sigma Chemicals. All other detergents used in this study were received from Affymetrix.

Fluorescence Measurements

CMC-determination

CMCs were determined with the set-up described earlier (36). In brief, Hoechst 33342 is highly fluorescence in hydrophobic environment whereas it is not in aqueous solution. Therefore, Hoechst 33342 fluorescence was monitored at increasing detergent concentrations. When fluorescence starts to increase (first inflection point), micelles start to form and interpolation leads to the CMC value.

Partitioning Coefficient determination

The partitioning coefficient of Hoechst 33342 into the micellar phase is given by equation 1:

$$P_{m(\text{Hoechst33342})} = \frac{[\text{Hoechst33342}]_m}{[\text{Hoechst33342}]_w} \quad \text{Equation 1}$$

As described earlier (38), one can calculate the partitioning coefficient by measuring the fluorescence intensity of the dye at different α_m values. α_m corresponds to the ratio of micelle volume to total volume of solution. If $F_m \gg F_w$, where F is the fluorescence of Hoechst33342, one obtains equation 2:

$$\frac{F}{F_\infty} = \frac{\alpha_m [\text{Hoechst33342}]_m}{\alpha_m [\text{Hoechst33342}]_m + (1 - \alpha_m) \frac{[\text{Hoechst33342}]_m}{P_m}} \quad \text{Equation 2}$$

F_{∞} corresponds to the fluorescence when all Hoechst33342 molecules are located in micelles. A plot of inverse fluorescence versus inverse α_m yields in a linear function, which provides the partitioning coefficient through the intercept divided by the slope (equation 3).

$$\frac{1}{F} = \frac{1}{F_{\infty}} - \frac{1}{P_m F_{\infty}} + \left(\frac{1}{P_m F_{\infty}} \cdot \frac{1}{\alpha_m} \right) \quad \text{Equation 3}$$

Steady State Fluorescence Quenching Studies

Detergent concentrations used in the assay were five fold above the CMC, determined with the method mentioned above, except for detergents with a very high CMC ($\geq 5\text{mM}$). In these cases, the detergent concentration above CMC was adjusted to 2mM. For example pure SDS aggregation number was measured at 10mM (CMC = 8mM). Pyrene concentration was adjusted to at least 10 fold below the concentration of micelles present as calculated from literature values for the aggregation number to avoid excimer formation. The quencher concentration varied from 0 to 20 μM .

Steady-state fluorescence quenching experiments were carried out either in a Fluorolog-3 (Horiba Jobin Yvon GmbH, Germany, Unterhaching) or in a 96well plate reader (Fluorostar, BMG labtech, Offenburg, Germany). Excitation wavelength was set to 335 nm (filter: 330 \pm 10 nm), emission was monitored from 365 to 450 nm or with a filter of 372 \pm 10 nm. Fluorescence data were corrected for background fluorescence and analyzed according to equation 4:

$$\ln \frac{I}{I_0} = - \frac{N[Q]}{(C_t - cmc)} \quad \text{Equation (4)}$$

Here, I and I_0 are the intensities of the first vibronic peak of the fluorescence emission spectra of pyrene in the presence and absence of several quencher concentrations. C_t is the total detergent concentration, N the aggregation number and cmc is the critical micellar concentration (107).

Theoretical treatment of mixed detergent systems: Ideal Mixing

To analyze whether it is really necessary to measure the CMC of the mixed detergent system or if one can rely on theoretical data we compared our data with the ideal mixing model (110). This model relates the ideal mixed CMC, CMC^* , with the experimental CMC of the pure components by using the following equations:

$$c_1 = x_1 CMC_1 = \alpha_1 CMC^* \quad \text{Equation (5)}$$

and

$$c_2 = x_2 CMC_2 = (1 - \alpha_1) CMC^* \quad \text{Equation (6)}$$

Equation (7) can be obtained after combining Equations (5) and (6):

$$\frac{1}{CMC} = \frac{\alpha_1}{CMC_1} + \frac{1 - \alpha_1}{CMC_2} \quad \text{Equation (7)}$$

where α_1 and x_1 are the mole fractions of detergent 1 (for example DDM) in the mixed solute and in the mixed micelle, respectively. CMC_1 and CMC_2 , c_1 and c_2 are the CMCs and the overall concentrations of components 1 and 2, respectively. If both detergents do not mix well one has to add the micellar activity coefficient f :

$$\frac{1}{CMC} = \frac{\alpha_1}{f_1 CMC_1} + \frac{(1 - \alpha_1)}{f_2 CMC_2} \quad \text{Equation (8)}$$

For a more detailed description of this theory, see Sarmoria et al. and Holland et al (111, 112).

Results

Here, we established a method to measure the CMC and aggregation numbers of detergents in a nearly high throughput manner. Due to the information gained with this assay it is possible to adjust buffer conditions of the purification and/or subsequent activity assay, in a controlled manner. For example it will be possible to maintain or regain MP activity and to stabilize the MP in a more controlled fashion (113, 114).

As recently described, fluorescence of Hoechst 33342 in detergent solutions can be used to calculate CMCs for different detergent-water or detergent-buffer systems (36). Hoechst 33342 is highly fluorescence in hydrophobic environments but shows nearly no emission in water-based solutes. In addition to the method to measure the CMC of detergent (36), we further developed an approach allowing the investigation of the influence of salts or pH on the CMCs and aggregation numbers of detergent mixtures .

To calculate aggregation numbers of detergents, pyrene quenching has been used extensively (38-40). Hoechst 33342 absorption spectra and pyrene fluorescence emission spectra overlap. This implicates that Hoechst 33342 can quench pyrene fluorescence in micelles as described in detail before (38, 39). Figure 1 shows fluorescence spectra of pyrene in the absence and presence of increasing Hoechst33342 concentrations. Here, the DDM concentration was 5 fold above CMC (1mM) and the pyrene concentration used was adjusted to an expected micelle to pyrene ratio of 10:1. Under these conditions no fluorescence peak at 470 nm was observed, which would have been present if pyrene excimers were formed.

To validate our method exercisable to determine aggregation numbers we needed to exclude possible errors introduced from poor solubility of Hoechst 33342 in different detergents. Therefore, we first analyzed the partitioning of Hoechst 33342 into different micelles. Partitioning coefficients (P_m) were calculated according to Equation 3 (see Materials and Methods). Hoechst 33342 greatly migrates into the micelles as shown by the P_m values listed in Table 1. The P_m value for DDM is 2500 demonstrating, that almost all Hoechst 33342 molecules are in the micellar phase under the conditions used in the assay. To phrase it

differently, 2500 fold excess of Hoechst 33342 is present in micelles compared to the aqueous phase. The same holds true for the other detergent tested (see Table 1).

As already observed earlier, micelle size is not strictly constant but varies slightly. With higher amounts of detergent, the micelle size in most cases also increases (38, 115, 116). Our assay is sensitive enough to reliably measure this increase. Pyrene quenching by Hoechst 33342 was analyzed measuring the emission peak of pyrene at 373 nm at different quencher concentrations. The intensity of pyrene fluorescence decreases with increasing quencher concentration (Figure 2). A plot of $\ln F/\ln F_0$ vs. quencher concentration results in a straight line from which the aggregation number can be calculated using the slope. Here an exact knowledge of the CMC and detergent concentration are an absolute prerequisite (see equation 4). Pyrene quenching was measured for three different DDM concentrations. Increasing DDM concentrations resulted in a decrease in the slope of the logarithmic fluorescence ratio, which is expected as the presence of more micelles decreases the probability to pair a donor and an acceptor molecule in the same micelle. The calculated aggregation numbers of 104, 135 and 154, respectively, correspond very well with literature values (see Table 2). To support our interpretation and the ease of our assay, we like to note that increasing aggregation numbers with increasing detergent concentrations were also observed with other techniques for example SANS, NMR, and SAXS (table 2) (38, 115-117).

As a second experiment, we looked at the influence of salt and pH on the behavior of the detergent in terms of CMC and aggregation number. Information about the influence of salt, pH, denatured reagents or further parameters on the physicochemical nature of a detergent micelle can be very useful to optimize buffer conditions especially to reduce the amount of free detergent or empty detergent micelles, when using MPs. Therefore, we analyzed the influence of increasing ionic strength on the aggregation number of SDS. DDM is a non-ionic detergent and shows only small changes in aggregation number under increasing salt concentrations as seen with other methods before (118). Therefore, we illustrated a more drastic example using SDS. In Figure 3, we measured SDS aggregation numbers without salt and after addition of 250mM sodium chloride. With increasing salt concentrations, the aggregation number increased from 68 for water to 86 (Figure 3). These

data are in good agreement with data obtained by the more sophisticated methods like ultracentrifugation (119), time-resolved fluorescence quenching (120), light scattering (121) and EPR (122), but we like to stress that this values were obtained in a 96well plate reader.

Often large micelles might stabilize a protein but interfere with activity or for example with the formation of crystal contacts (106). With the pyrene quenching method it is possible to measure several detergent mixtures in a 96-well plate reader in a couple of hours. Figure 4 shows exemplary mixtures of DDM with other detergents. DDM is a very widely used detergent for MP purification and activity measurements. The different ratios of DDM with the added detergent where analyzed for their influence on CMC and aggregation number and plotted against the molar ratio of added detergent. Most of the calculated CMCs show almost ideal behavior according to equation (7), which is highlighted by a straight line. Here, we refer to the pseudo phase thermodynamic model described by Clint and Motomura (110, 123). In our study, little deviation from ideal behavior is observed only for example for high amounts of SDS in DDM micelles. As seen in Figure 4, the measured values for CMCs (triangles), when more than half of the detergent present is SDS do not increase with the same intensity as the straight line indicative for ideal behavior does. For example, for 90% SDS in the detergent mixture, we observed a CMC of 1mM whereas theoretically it should be 1.54 mM. The same deviation for this mixture was observed with surface tension measurements by Zhang et al. (124). Therefore, one has to be careful when mixing detergents with dramatic differences in CMC and different head groups (nonionic vs. ionic). The reason for this deviance might be poor mixing in the micelle of the two components. This is an important information when choosing to work with a mixture of detergents.

The aggregation numbers plotted in Figure 4 seems to behave linear in most mixtures with DDM, which is in good agreement with data obtained by SAXS studies on mixed micelles (125). Only SDS and Triton X-100 show unexpected curve progression. SDS seems to have little impact on DDM as also seen in CMC behavior (see above). The aggregation number stays roughly 100 until 100% SDS is reached, where a value of 50 monomers per micelle was calculated. For Triton X-100 the observation is the opposite: here aggregation number increases already after the addition of 25% Triton X-100 to DDM from 108 to 189.

These findings strongly recommend investigating the CMC and aggregation number of the detergent mixture in the buffer used before the experiment is started.

Discussion

Quenching of pyrene fluorescence by Hoechst 33342 can be used as a simple and rapid method to determine aggregation numbers. Together with the usage of a 96well plate reader ten or more detergent mixtures can be measured in less than an hour. Pyrene was chosen due to its long fluorescence lifetime ($\approx 400\text{ns}$)(126), but also because it is relatively cheap and widely available.

Hoechst 33342 partitions greatly into the micellar phase and shows an overlap with the pyrene fluorescence spectrum. Furthermore, it does almost not fluorescence in the region of pyrene fluorescence peak maximum (273 nm). Hoechst 33342 fluorescence can be used to determine CMC values (36). Combining both characteristics gives the opportunity to determine aggregation numbers with equipment that is literally available in every biochemical lab. Of course other combination of fluorophore and quencher are possible and might be investigated. Furthermore, the physical behavior of detergent mixtures can be measured using basically every imaginable ratio of detergent. We show here the proof of principle using DDM as the first detergent. To the best of our knowledge this method is applicable for any detergent.

Figure 1: Corrected emission fluorescence spectra of a 5.0×10^{-7} M solution of pyrene in an aqueous solution of 1 mM DDM at 25°C. The black curve was collected in the absence of the quencher Hoechst 33342; grey and blue curves in the presence of increasing (5 to 20 μ M) quencher concentrations.

Figure 2: Quenching of Pyrene fluorescence by Hoechst 33342 at three different detergent concentrations. The logarithm of the fluorescence intensity of the first vibronic peak of pyrene is shown as a function of Hoechst 33342 concentration. Pyrene was excited at 335 nm and emission monitored at 372 nm. Aggregation numbers were calculated from the slope of these three measurements and are 104, 135 and 154, respectively.

Figure 3: Salt dependency of aggregation number of SDS. Increasing salt concentrations result in a swelling of the micelle. Aggregation numbers calculated from this plots resulted in a value of 68 and 86 monomers per micelle, respectively.

Figure 4: CMC and aggregation number determination of mixtures of DDM with different detergents via the 96-well plate reader set-up. Triangles show the behavior of the CMC at different ratios of a second detergent. Quadrangles indicate aggregation number measured for different detergent mixtures.

Type I secretion

Abstract

The ABC transporter haemolysin B (HlyB) from *E. coli* is part of a Type 1 secretion system that translocates a 110 kDa toxin in one step across both membranes of this Gram-negative bacterium in an ATP-dependent manner. Sequence analysis indicates that HlyB contains a C39 peptidase-like domain (C39-like) at its N-terminus. C39 domains are thiol-dependent peptidases that cleave their substrates after a GG motif. Interestingly, the catalytically invariant cysteine is replaced by a tyrosine in the C39 domain of HlyB. Here, we describe overexpression, purification and crystallization of the isolated C39 as a first step to obtain structural insights into this domain and eventually answer the question concerning the function of a degenerated C39 in the ABC transporter HlyB.

Introduction

The ATP-binding cassette (ABC)-transporter HlyB is a central element of the Type I secretion machinery of *Escherichia coli* (*E. coli*). Together with the inner membrane protein HlyD which interacts with the outer membrane protein TolC, HlyB forms a continuous channel-tunnel from the cytoplasm into the exterior to secrete the 110 kDa toxin HlyA without any periplasmic intermediates (42, 129-132).

In general, a functional ABC transporter consists of two nucleotide-binding domains (NBD) and two transmembrane domains (TMD). However, and in contrast to this general blueprint, HlyB contains an additional N-terminal domain of about 150 amino acids that is conserved in bacteriocin ABC transporters (45, 133). A sequence alignment classifies the N-terminal region of HlyB as a C39 domain. This family of cysteine peptidases cleaves their substrate after a GG-motif using a catalytic dyad consisting of a conserved cysteine and a histidine. In HlyB, however, the catalytic dyad is degenerated; the highly conserved cysteine residue is mutated to tyrosine (45, 133). Thus, this domain is very likely inactive giving rise to the name C39-like domain.

Curiously, the C39-like domain of HlyB appears to be essential for secretion of the toxin HlyA. In a system where HlyB lacks the C39-like domain, secretion of HlyA is completely abolished (data not shown) and therefore the question arises what specific role this defective protease may play during substrate secretion. We expressed and purified the C39-like domain in *E. coli* and with the objective determine its structure using X-ray crystallography. Here, we describe the preliminary results of the crystallization of C39 of HlyB from *E. coli*.

Material and Methods

Cloning, expression and purification

E. coli strain BL21 (DE3) pLysS was transformed with the vector pET28b harboring the HlyB-C39 gene for overexpression of the C39-like domain (residues 2-144 of HlyB). Since the original sequence of the C39-like domain contains no methionine, two isoleucines were exchanged for methionine to facilitate the possibility the introduction of selenomethionines to provide a tool for structure determination by anomalous diffraction. Cells were grown at 37°C and 180 rpm in the rich medium (2xYT) until an OD₆₀₀ of 0.6 before expression of the C39-like domain was induced by addition of 1mM isopropyl β-D-thiogalactopyranoside (IPTG). All following steps were performed at 4°C. Cells of 4 L bacterial cell culture were harvested 5 h after induction by centrifugation and re-suspended in 60 mL 50 mM HEPES pH 7.0, 150 mM NaCl, 10 % (v/v) glycerol. After addition of DNase (0.1 mg/mL) cells were incubated for 20 min and disrupted three times with 2.5 kbar using a cell disrupter (Constant Systems). The homogenate was centrifuged for 30 min at 30,000 x g. The expression of the C39-like domain resulted in the formation of inclusion bodies. The pellet of inclusion bodies was washed once with 50 mM Tris-HCl pH 7.0, 0.5 % Triton X-100, 1 mM dithiotreitol (DTT), 0.05 % NaN₃ and once with 50 mM Tris-HCl pH 7.0, 1 mM EDTA, 0.05 % NaN₃. Following the final centrifugation step, inclusion bodies were resuspended in 20 mL buffer (6 M guanidinium hydrochlorid, 10 mM Tris-HCl pH 7.0, 100 mM KCl, 10 mM DTT) until the pellet was dissolved. The protein suspension was centrifuged for 1 h at 50.000 x g and the protein concentration of the supernatant was determined using a NanoDrop device (PeqLab Biotechnology GmbH). The resulting supernatant was diluted to 2 mg/mL with resuspension buffer and dialyzed overnight in a 1:125 ratio against renaturation buffer containing 50 mM Tris-HCl pH 8.0, 100 mM NaCl, 1 mM EDTA, 10 % (v/v) glycerol, 2 mM DTT, 0.5 % (w/v) PEG 3350 using dialysis tubing with a molecular weight cut-off of 6-8 kDa (Spektra/Por, Spectrum Laboratories, CA, USA). After dialysis any precipitate was separated from soluble protein by centrifugation for 10 min at 21,000 x g and the supernatant was applied to a cation-exchange (cIEX) chromatography (5 mL SP HP column, GE Healthcare) pre-equilibrated with buffer A (10 mM HEPES pH 7.0, 1 mM DTT). After washing with 5 column

volumes (CV) of buffer A, proteins were eluted with a linear gradient of 40 CV to 100 % buffer B (buffer A containing 500 mM NaCl). Proteins eluting at 190 mM NaCl (38% buffer B) and 375 mM NaCl (75 % buffer B) were concentrated using an Amicon Ultra Centrifugal Filter device (10 kDa MWCO, Millipore), and analyzed by SDS-PAGE and Western blotting with an antibody recognizing the His-Tag (according to the manufacturer, Qiagen). However, the protein fraction that eluted at 375 mM NaCl from the column could not be concentrated above 2 mg mL⁻¹. Nevertheless, both species were applied to a size exclusion chromatography (SEC) using a Superdex-200 16/60 column (GE Healthcare) equilibrated with 50 mM Tris-HCl pH 8.0, 150 mM NaCl, 1 mM DTT.

Buffer Screen

A buffer screen was performed with the C39-like domain fraction eluting at 375 mM NaCl during cIEX chromatography. The protein was concentrated immediately after elution to 2 mg mL⁻¹. 300 nL of the C39-like domain were mixed in a 1 : 1 ratio with commercially available crystallization buffers (Basic Crystallography Kit, Sigma-Aldrich) in 96-well plates using a pipette robot and incubated at 18°C for 24 h. Buffer conditions with no visible precipitations were analyzed further. 1 mL of the C39-like domain (2 mg mL⁻¹) was dialyzed against 1 L of each buffer positively evaluated in the 96-well format using Slide-A-Lyzer dialysis cassettes (10 kDa MWCO, ThermoScientific) and subsequently concentrated via filter devices (see above) until precipitations occurred. After purification and dialysis against 50 mM citrate pH 6.5 and 20 mM LiCl, the C39-like domain could be concentrated to 20 mg mL⁻¹.

SEC-MALS

SEC-MALS (SEC - multi-angle light scattering) experiments were performed using an analytical Superdex200 10/300 column (GE Healthcare) equilibrated with 25 mM Tris pH 8.0 and 150 mM NaCl on an Äkta-Purifier (GE Healthcare) connected to a triple-angle light scattering detector (miniDAWN™ TREOS, Wyatt Technology) followed by a differential refractive index detector (Optilab® rEX, Wyatt Technology). 100µL of purified C39-like domain was loaded at a protein concentration of 1 mg mL⁻¹ on the analytical Superdex200 10/300 column. Data were analyzed with the ASTRA software package (Wyatt Technology).

Crystallization and preliminary X-ray analysis

Crystallization conditions were screened via the sitting-drop vapor-diffusion method in combination with commercially available buffers (Sigma basic screen I and II) using the monomeric as well as oligomeric form of the C39-like domain at a protein concentration of 20 mg/ml. Crystals appeared when samples of protein were mixed with an equal volume of the precipitant solution containing 3.6–4 M formate. Using the “No-fail cryoprotection” method (<http://capsicum.colgate.edu/chwiki/>) 37.5% glucose in mother liquor was added gradually to the crystal solutions to a final concentration of 20% glucose before flash cooling of the crystals in liquid nitrogen. A high resolution dataset was collected from a single crystal at 100 K at a wavelength of 0.87260 Å on a MAR225 detector (MAR Research) at the ESRF beamline id23eh1 using a 0.75° rotation per frame. The dataset was processed using the XDS Package (74) and scale using XSCALE.

Results and discussion

The C39-like domain of HlyB was expressed as inclusion bodies in *E. coli*. After preparation and crude purification of the inclusion bodies, proteins were denatured and refolded. A cIEX step was used to purify the refolded C39-like domain (see methods). During elution with a salt gradient, two species eluted at 190 mM NaCl (38% Buffer B) and 375 mM NaCl (75% Buffer B), respectively (Figure 1). SDS-PAGE and Western Blot analysis using an anti-His-tag antibody showed that both eluted fractions correspond to the C39-like domain (data not shown). Therefore, both species were concentrated and applied to a SEC column. However, the resulting elution chromatograms were different. The low-salt species (190 mM NaCl) gave two peaks (61 mL and 93 mL) corresponding to an oligomeric and a monomeric species. Based on a calibration curve the molecular weights were calculated to approximately 200 kDa and 20 kDa, respectively. For further investigation of the molecular weight of the low salt oligomeric species more precise MALS experiments were performed and the molecular weight was determined to be 233.4 ± 1.4 kDa, corresponding to a dodecamer of the C39-like domain (Figure 2). Analysis by size exclusion chromatography of the high-salt species (375 mM NaCl) revealed that species that corresponded only to a monomeric C39-like domain.

The monomeric species precipitated at a relatively low protein concentration of 2 mg mL⁻¹. In our hands, this concentration was too low to obtain any protein crystals since more than 90% of the drops in the crystallization experiments did not show any precipitation at such low protein concentration. Therefore, a buffer screen was performed to search for conditions with enhanced solubility and stability of the C39-like domain using commercially available crystallization screens. As read-out we chose to rely on visible aggregation, which was evaluated one day after setting up the buffer-protein mixtures. The C39-like domain in buffers resulting in no visible precipitations was spun down using ultracentrifugation and the concentration of the C39-like domain was determined in the supernatant. This method revealed a buffer condition in which the protein was more stable; 20 mM citrate pH 6.5, and 20 mM NiCl₂. Monomeric C39-like domain, originally precipitating at 2 mg mL⁻¹, could be concentrated above 20 mg mL⁻¹ and was stable for weeks when dialyzed against this buffer

directly after refolding. Unfortunately, despite extensive efforts no well diffracting crystals of the C39-like domain could be obtained.

Therefore, we went back to the initial oligomeric species and crystallized this form of the C39-like domain. Crystals were observed in various screening conditions. The best diffracting crystals (Figure 3) were obtained after 30 d at 12°C in 3.6 - 4 M Na-formiate. For diffraction analysis, crystals were cryoprotected using a "No-fail cryoprotection" method (<http://capsicum.colgate.edu/chwiki/>). Here, crystal-containing drops were substituted step by step with small volumes of 37% glucose dissolved in mother liquor to a final glucose concentration of 20%. With this method well-diffracting crystals could be obtained and a native dataset was collected.

Preliminary analysis of the dataset using the XDS package revealed that the crystals belong to the primitive orthorhombic space group (either P2₁2₁2 or P2₁2₁2₁) with a large unit cell axis ($a=117.6$, $b=134.2$ $c=139.4$ Å) for a protein of this size. At the moment, we cannot distinguish between both space groups, since the systematic absences observed are not conclusive. The overall dataset was cut off at a resolution of 2.1 Å with an R_{merge} value in the highest resolution shell below 30% (see Table 1 for data statistics). Consideration of the unit-cell volume (2.2×10^6 Å³) and the molecular weight of 19,460 Da suggests that the asymmetric unit contains either one copy of 12mer corresponding to a V_M value of 2.36 Å³ Da⁻¹ with an estimated solvent content 47.61% (134).

This suggests that the initially observed oligomeric species is likely the state in which the C39-like domain is in a sufficiently stable and homogenous state to crystallize under the conditions used in this study.

An attempt to solve the structure of C39-like taking advantage of the introduced selenomethionine residues for usage of multiple anomalous dispersion (MAD) phasing is currently under way. The result of this structural analysis should provide an insight into the function of C39-like of HlyB, and its role in the secretion of HlyA.

Acknowledgments

We would like to acknowledge Solvej Siedler for important assistance during the initial stages of the project. We greatly acknowledge financial support from the EU (EDICT program) to L.S. We thank the Ministry of Innovation, Science, and Research of the German Federal State North Rhine-Westphalia (NRW) and the Heinrich Heine University Düsseldorf (scholarship from the CLIB-Graduate Cluster Industrial Biotechnology to C.S.).

Introduction

Type-1 secretion in *Escherichia coli* or other Gram-negative bacteria allows the translocation of a wide variety of substrates from cytoplasm to the extracellular space in a single step, without periplasmic intermediates (1). In contrast to Sec-dependent translocations, information required and sufficient for secretion, the secretion signal, is located at the very C-terminus of the substrate and not cleaved after translocation.

The paradigm of a Type I secretion system is the Haemolysin A (HlyA) secretion system. The translocation complex is composed of three different proteins: An ABC-Transporter, HlyB in the inner membrane, the membrane fusion protein HlyD, that is supposed to seal the translocation pore of HlyB and the outer membrane protein TolC. HlyD spans the membrane a single time with the first 60, N-terminal amino acids being located in the cytosol. However, the role of this putative cytoplasmic domain remains unclear although deletion abrogates substrate secretion (2). The ABC-transporter HlyB is supposed to act as a dimer and therefore contains two transmembrane domains (TMDs), two nucleotide binding domains (NBDs) and additionally to "classic" ABC-transporters, a C39 peptidase domain at its N-terminus. In general C39 domains cleave their substrates after a canonical double glycine motif. However, and as mentioned before HlyA is not degraded during translocation (see Chapter VI). This is due to the fact that the C39 domain of HlyB is degenerated, i.e. the amino acids required for cleavage activity, a cysteine and an aspartate are missing. As this domain is on the other hand essential for toxin secretion it must play a role in substrate recognition, stabilization during transport or communication with other components of the secretion complex.

Despite the fact that the ATP hydrolysis cycle of the NBDs of HlyB is rather well analyzed and understood (3-6), little is known about interaction and regulation of the whole transport complex. Therefore we purified the inner membrane components of the secretion system and investigated the interplay of HlyB and the substrate HlyA using ATPase activity measurements as a read-out.

Materials and Methods

Materials

Fos-choline14 was obtained through SynphaBase (Pratteln, Switzerland). Octaethylene glycol monododecyl ether (C₁₂E₈) was supplied from Affymetrix (Santa Clara, USA). All other chemicals were purchased from Sigma-Aldrich at the highest purity available.

Strains and Plasmids

pLG814 (7) encoding HlyB and HlyD was used as template for HlyB and the HlyB sequence lacking the C39 peptidase domain (HlyB Δ C39). By standard PCR methods nucleotides encoding amino acids 1-707 (HlyB) were amplified. Primers were as follows: HlyBfor 5'GCTATCCATGGCGAATICTGATTCTTGTCATAAAATTGATTATGGG3'; HlyBrev 5'CGTGTCTAGATTACAGGATCCCGTCTGACTGTAAGTATAAGTAACTG3'. Underlined sequences encoded restriction sites for cloning purposes (EcoRI/BamHI). The HlyB sequence was cloned into pET401 vector using compatible, cohesive ends. Introduction of the affinity tag with a protease cleavage site (factor Xa) was performed postcloning by addition of an oligonucleotide pair at the 5' end (N-terminus; Nhis10Eco_for: 3'AATTCTCATCACCATCACCATCACCATCACCATCATAGCATCGAAGGGCGC5', Nhis10Eco_rev: 3'AATTGCGCCCTTCGATGCTATGATGGTGATGGTGATGGTGATGGTGATGAG5'). The final gene was further subcloned into pBAD vector yielding pSJ027.

HlyB Δ C39 plasmid is based on pSJ027 and gained with In-Fusion kit from Clontech (8). The gene of interest was amplified using the following primer sequences: CATCACCATCACCATCACCATCATGAGAATCTTTATTTTCAGGGCGCTTCCCGTTCTTCTGTTC and GGCGGCCGCTCTAGATTACAG. The vector was linearized using the following primers: TCTAGAGCGGCCGCCACCG and ATGGTGATGGTGATGGTGATGAGAATTCGCCATGGT, respectively. Correctness of all constructs was verified by sequencing.

For HlyA secretion experiments same constructs as described in Bakkes et al. were used (9).

Protein overexpression and purification:

E. coli strain BL21 (DE3) was transformed with plasmid pSJ027 coding wild type or mutant (H662A, Δ C39) His₁₀-tagged HlyB protein. Cultures in 2litres of 2YT medium were grown at 37°C until the OD₆₀₀ reached 0.8, induced by the addition of arabinose (final concentration of 10mM) and were grown for an additional hour. Cells were harvested by centrifugation; cell pellet was resuspended in buffer R (50mM Tris/HCl pH 8.0, 150mM NaCl and 10% glycerol) and

lysed by three passages through a cell disruption machine at 2.5kbar (IUL systems). The cell lysate was centrifuged at 18,000xg for 30min before membranes were isolated by ultracentrifugation (125,000 g, 90min). The resulting membrane pellets were homogenized in buffer M (50mM Tris/HCl, 250mM NaCl, 10% Glycerol). Membrane vesicles were lysed with 1% Fos-choline 14 and HlyB was purified using HiTrap Chelating column loaded with Zn²⁺ (GE Healthcare). The buffer employed was 50mM Tris/HCL, 250mM NaCl, 10 or 200mM Imidazol and 0.012% (w/v) C₁₂E₈. His-tagged protein was eluted with 150mM Imidazol and subsequently loaded on a gelfiltration column (Superose6 10/300 GL, GE Healthcare). Protein fractions were analyzed by SDS-PAGE according to Laemmli (10), using a 10% acrylamide gel, followed by staining with Coomassie Blue.

HlyA secretion

Plasmids encoding for HlyB/HlyD (pSJ037) and HlyA (pSUI) were transformed in BL21 DE3 cells. HlyA secretion was performed for 6h until cells were separated by centrifugation and subsequently supernatant was filtered through 0.25µm filter. Supernatant was concentrated and loaded on a Superdex200 16/60 gelfiltration column (GE Healthcare). Elution fractions containing HlyA were analyzed by SDS-PAGE, shock frozen in liquid nitrogen and stored at -80°C until further use.

Static light scattering

SEC-MALS (SEC and multi-angle light scattering) experiments were performed using an analytical Superose6 10/300 column (GE Healthcare) equilibrated in 50mM Tris pH 8.0, 150mM NaCl run on an Äkta-Purifier (GE Healthcare) connected to a triple-angle light scattering detector (miniDAWN™ TREOS, Wyatt technology) followed by differential refractive index detector (Optilab® rEX, Wyatt technology). Purified HlyB was loaded at 1.5 mg mL⁻¹ with a sample size of 100ul. Data were analyzed with the ASTRA software package (Wyatt Technology).

ATPase activity assay

The purified HlyB was assayed for ATP hydrolysis using the Malachite Green method, which depends upon release of P_i and performed as described in (11). Assays were performed at 22°C in a temperature controlled 96-well plate spectrometer (Fluostar, BMG labtec). Reaction mixture contained 10mM MgCl₂ and increasing amounts of ATP or HlyA.

Results

Isolation and Purification of HlyB:

N-terminally His₁₀-tagged *E. coli* HlyB was overexpressed in *E. coli* BL21 DE3 cells and purified by affinity chromatography followed by gel filtration. As the choice of the detergent used had a great impact on oligomeric status and activity of HlyB detergent was exchanged during affinity chromatography. Nonionic, zwitterionic and ionic headgroups as well as different chain length of detergents were tried. Best results in terms of activity were obtained using nonionic detergents of rather low CMC and more than 100 monomers per micelle (for example DDM and C₁₂E₈).

Purified HlyB in C₁₂E₈ buffer solution was >95% pure (Fig 1). Minor contamination at 50 kDa corresponds to a degradation product, which could be confirmed by western blot analysis using polyclonal antibody against the NBD of the transporter (data not shown). A typical preparation from 4 liters of bacterial culture yielded 5 mg of pure membrane protein.

Figure 1: Purification of HlyB. The HlyB dimer is observed at a molecular weight of around 140kD, the monomer runs at 70kD.

Both HlyB mutants (H662A, HlyB Δ C39) could be obtained in same quality and amounts following this procedure.

Secretion and purification of HlyA

Highly pure secreted HlyA was further purified by size exclusion chromatography (Fig 2) After concentrating the supernatant residual medium components could be removed with this step.

Figure 2: A: 10% SDS-PAGE of purified HlyA. Observed band of a molecular weight of 110kDa belongs to HlyA. B: Blue Native Page of purified HlyA. First lane shows HlyA after incubation at 65°C with SDS, second lane shows HlyA running without denaturing agents.

Blue Native PAGE analysis was tried to identify the oligomeric state of HlyA after secretion. However, comparison of unfolded and native protein is rather delicate as the unfolded protein (treated with SDS and incubated at 90°C) runs at a higher molecular mass as expected (approx. 250kD). Therefore the slower migration of the folded protein indicates a dimeric form of the protein but clearly needs further analysis for verification.

Static light scattering to verify the oligomeric state

Online multi-angle light scattering experiments were performed to analyze the oligomeric state of HlyB in detergent solution.

Figure 3: Gelfiltration profile of HlyB on a Superose6 column (GE Healthcare). Blue line: UV-Absorption at 280nm, Red line: Light scattering signal at an angle of 90°, Black line: molar mass, purple line: molar mass of the protein fraction, Green line: molar mass of the detergent fraction.

The results in Figure 3 confirm the dimeric status of purified HlyB in detergent solution as expected for an ABC-transporter. HlyB dimer accumulates roughly the same mass of detergent to stay in solution. The whole protein detergent complex has a calculated molar mass of 301kD, while protein fraction is 155kD. The mass decay in Figure 3 clearly indicates that our preparation is not homogeneous in terms of detergent-protein ratio. However, as we can show specific activity for HlyB, this issue is neglected.

ATPase activity of isolated HlyB

ATPase activity of wildtype HlyB was monitored over 20min and at ATP concentration ranging from 0 to 2mM. Resulting data did not obey Michealis-Menten kinetics, while a nearly perfect fit was obtained using the Hill equation. Such cooperativity has been also observed for the isolated HlyB-NBD but not for example for HisP, MalK or Mdl1p NBD (12-14). Kinetic data are summarized in **Table 1**. It was shown previously that mutation of H662 to Ala abolished ATPase activity for the isolated NBD (3). Therefore this mutation was introduced in full length HlyB by site-directed mutagenesis and also assayed for ATPase activity. As expected no activity could be detected under the conditions tested for the wild-type protein (Fig 4)

Figure 4: ATPase activity measurements of HlyB in detergent solution. Triangles show HlyB wt activity, squares: HlyB H662A mutant, rotated squares: HlyBΔC39.

Table 1: Kinetic data of HlyB ATPase activity

	K_M in mM	V_{max} in nmol/min/mg	h	K_d in μM
HlyB wt	0.42	15.3	2	21.01
HlyB $\Delta C39$	2.00	51.0	-	26.80
HlyB_NBD (3.6 μM)	0.26*	600*	1.35*	4#
(1.1 μM)	0.36*	202	1.31*	

* Zaitseva et al. 2005 (3) #Benabdelhak et al. 2003 (15)

For some ABC-transporter stimulation of ATPase activity after addition of substrate could be detected (16). Interaction of HlyB and HlyA were substantiated by two individual methods (pull-down assays with the separated C39 domain (see Chapter VI) and C-terminal fragment of HlyA, Biacore measurements with HlyB-NBD and HlyA fragment (15) as well as C39 domain and this fragment (own lab, unpublished data). Therefore we analyzed the impact of HlyA on the ATPase activity of HlyB (Fig 5) and investigated the impact of the C39 domain. To see if the C39 domain is involved in regulation of the transporter, we deleted the first 150 amino acids of the full-length transporter and measured the remaining ATPase activity (Fig 5) HlyB $\Delta C39$ shows more than four fold higher ATP turnover than wild type protein (Fig 4). As stability is increased for this truncation mutant we assume that this effect is not physiologically relevant.

However measurement of activity in presence of increasing amounts of HlyA showed a stimulation of the ATP-hydrolysis rate for the full-size transporter as well as for the $\Delta C39$ version (Fig 5)

Figure 5: Left panel: HlyA dependent ATPase activity of HlyB full-length and truncation of C39. Increasing amounts of HlyA stimulate ATP hydrolysis rate leading to K_D values of 21 and 26 μM , respectively. Right panel: SDS-PAGE showing purified HlyB $\Delta C39$.

Interestingly this effect is more than six fold larger for the truncation mutant. Affinity constants are in the same range namely 21 ± 4 and $26 \pm 3 \mu\text{M}$ (Fig 5) for wild type protein and ΔC39 , respectively. This is in line with the measured interaction by SPR where a K_D of $4 \pm 2 \mu\text{M}$ was determined for HlyA (25kD, see below) to the isolated HlyB-NBDs (15). As C39-domains are known for cleaving their substrates after double glycine motifs we checked if this stimulation effect relies on the signal sequence at the HlyA C-terminus or on GG-repeats in front of it.

Figure 6: Impact of different variants of HlyA of ATPase activity of HlyB Δ C39. HlyA25kD includes the 216 amino acids of the C-terminus of HlyA. HlyA_wOSS consists of amino acids 807-966, starting at the same amino acid as the other fragment but lacking the last 57 amino acids at the very C-terminus, i.e. the secretion sequence. HlyA variants were added at a concentration of 3 μM , ATP concentration was 1mM.

Figure 6 summarizes the ATP-hydrolysis rates of HlyB Δ C39 in the presence of different HlyA proteins. The figure clearly shows, that the secretion sequence is the important determinant of ATP-hydrolysis stimulation. Full-length as well as a 25kDa C-terminal fragment enable HlyB Δ C39 to hydrolyze additional 0.4 ATP molecules per minute (0.41 ± 0.064 ATP/min for full length HlyA, 0.36 ± 0.033 ATP/min for 25kDa HlyA). This effect cannot be detected if a degradation fragment of 25kD-HlyA lacking the 57 C-terminal amino acids corresponding to the secretion sequence is added.

Our results suggest a transport mechanism where HlyA has to bind to the C39-like domain via its glycine repeats but the secretion sequence triggers the ABC-transporter to hydrolyze ATP and fuel the transport process with energy.

Discussion

Homologous expression of the Type I secretion system component HlyB and the substrate HlyA in *E. coli* yield sufficient amount of both proteins. We successfully isolated HlyB from the membrane fraction of *E. coli* and prepared membrane vesicles to extract the protein from. However this step was quite challenging as only Fos-choline14 and 16 were able to extract more than 30% of HlyB from the membrane. Moreover one has to handle these detergents with care as several former studies have stated that especially these zwitterionic harsh detergents tend to unfold proteins (17). Our study also resulted in inactive protein in buffers containing FC14 (data not shown). Thus we exchanged the detergent right after extraction and screened for a detergent that stabilizes HlyB in an active conformation. This screening resulted in a protocol using FC14 and C₁₂E₈. With this method HlyB could be maintained in its dimeric state, which was proven by size exclusion chromatography with online light scattering analysis. After two purification steps HlyB was more than 95% pure and showed low basal ATPase activity, with a $K_{0.5}$ constant in the range as determined for the isolated NBDs (3)

Any uncertainty concerning the detergent can be ruled out if the activity of the protein can be proven and especially if you can detect specific activity. As the light scattering data showed that our preparation is slightly inhomogeneous in terms of protein-detergent ratio, we could dispel all doubts by detecting HlyA dependent ATPase activity. Furthermore, the H662A mutant of full-length HlyB displayed no activity sustaining our interpretation. Former data on the isolated HlyB-NBDs demonstrated an interaction of the NBDs with the secretion signal at the C-terminus of the substrate HlyA using Biacore measurements (15). Here it was possible to confirm these data on full-length protein with ATPase activity measurements as hydrolysis rate increased when adding increasing amounts of substrate and follows a one-site binding kinetic. A modulation of ATPase hydrolysis upon substrate addition has been reported for several ABC-transporters (18-20). In line with these reports one can imagine that the substrate might induce a more efficient dimerisation of the NBDs compared to dimer formation upon binding of the loaded substrate binding protein in import systems.

To rule out the role of the additional N-terminal extension of HlyB, the C39-domain, this domain was removed genetically and the same purification protocol as for wild type protein was applied. When comparing HlyA dependent ATPase activity of wild type and Δ C39 protein Δ C39 shows six fold higher stimulation than wild type, but most importantly no HlyA stimulation was detectable. Thus C39 domain has a regulatory role on ATP hydrolysis during transport and ATP hydrolysis appeared to be uncoupled if this domain is lacking.

Danksagung

An allererster Stelle möchte ich mich hier bei Lutz bedanken. Für die Freiheiten, die Du mir gegeben hast, für die Freude, die Dir ein SDS-Gel bereiten kann, aber auch den Einsatz für mich in jeglicher Hinsicht, egal ob es nur um die Abschlussfeier ging, die Verwaltung oder Messzeiten.

Sander, Du hattest Recht: „Ich hab immer zu Dir gehört!“. Wo soll ich da anfangen? Danke für die vielen Stunden Deiner Freizeit, die Du mit mir am Synchrotron verbracht hast, für die Zeit, die Du in den letzten Monaten in meine Arbeit hier gesteckt hast, dafür, dass Du immer nach pragmatischen Lösungen suchst, dass Du ganz im Gegenteil zu mir Deinen Blutdruck im Griff hast, einfach für mittlerweile fast vier lehr-/ erfolgreiche und auch schöne Jahre.

Danke Thorsten! Für jeden *Abstract*, den Du nicht nur in eine allgemein verständliche Sprache gebracht hast, für all die *Sampler*, die ich gebraucht habe, für Deine einfachen Lösungen, dafür, dass Du es geschafft hast eine Laborbank mit mir zu teilen (ich weiß, dass das sicher nicht einfach war und Spuren hinterlassen hat); und nicht zu vergessen: die schönen Cocktailstunden am Abend....

Mir ist bis heute nicht klar, wie ein Mensch so viel Geduld und Ruhe ausstrahlen kann, wenn einem kleine naive Mädels monatelang hinterherlaufen und immer noch nicht den Unterschied zwischen Marker und Laufpuffer kennen? Vielen Dank, Stefan, für Deinen Enthusiasmus und Deine Hingabe für die Arbeit im Labor. Dank Dir habe ich sicher eine der besten Entscheidungen in meinem Leben getroffen.

André Du musst auch mal „Nein“ sagen.... Aber ich bin Dir sehr dankbar, dass Dir dieses Wort bisher immer gefehlt hat, wenn ich Dich brauchte.

Vielen Dank, Silke! Immer wenn ich Dich gebraucht habe, warst Du zur Stelle: Korrekturlesen, Kaninchen hüten, mich quer durch das Land fahren, u.v.m., alles kein Problem für Dich gewesen. Ich hoffe, dass das auch so bleiben wird.

Danke, Christian, dass Du wieder ein bisschen Schwung in die Bude gebracht hast. Es macht einen Riesenspaß mit Dir an einem Projekt zu arbeiten!

Nun zum stillen Lexikon in unserem Büro: Nils! Danke, dass Du immer da warst um uns vor groben Unfug zu bewahren. Ich glaube nicht, dass ich mich erinnere mal von Dir keine Antwort bekommen zu haben.

Petra wie Du siehst habe ich doch noch das mit den ATPasen in den Griff bekommen (und einen eigenen Standard hab ich nicht!). Vielen Dank für den ausgleichenden Pol in unserer Ecke. Und das Parkbank Event verlangt noch nach Wiederholung.

Jan und Philipp: Blots und DNA!!!! Beides Dinge, die ich nicht beherrsche! Schön, dass Ihr mir da immer zur Seite standet.

Vielen Dank Frau Blum, dass sie mir den ganzen unwegsamen Verwaltungsaufwand abgenommen haben. Ohne sie wäre ich spätestens nach einem halben Jahr insolvent und ohne Arbeitsvertrag gewesen!

Mein Dank gilt auch allen meinen anderen Kollegen, die vieles erst ermöglicht haben.

Und dann noch die hilfsbereiten, zuverlässigen und allzeit bereiten Partner in Marburg: Danke Marco und Erhard!

Schließlich die Menschen außerhalb der Forschung: Meine Eltern und Geschwistern, sowie mein Freund Kevin: Ohne Eure Unterstützung über die ganzen Jahre hinweg wäre vieles nicht möglich gewesen. DANKE!

Lebenslauf

Persönliche Daten:

Name: Britta Tschapek
Geburtsdatum, -ort: 16.02.1984, Viersen
Familienstand: ledig
Staatsangehörigkeit: deutsch

Hochschulausbildung

11/2007: Beginn der Promotion am Institut für Biochemie in der Arbeitsgruppe von Prof. Dr. Lutz Schmitt
Thema: Biophysical characterization of ABC transporters catalyzing import and export function

10/2007: Abschluss zur Diplom Wirtschaftchemikerin
Titel der Diplomarbeit:
Einzelmolekül-Fluoreszenzspektroskopie an der ABC-ATPase OpuAA in Liposomen
Angefertigt im Institut für molekulare physikalische Chemie der Heinrich Heine Universität Düsseldorf, Prof. Dr. Claus A. M. Seidel

10/2003-10/2007 Studium der Wirtschaftchemie an der Heinrich Heine Universität Düsseldorf.

Schulbildung

8/1994-7/2003 Clara-Schumann-Gymnasium Dülken
8/1990-7/1994 Martinschule Süchteln
